3. It is cheap, simple and withal efficient.

4. It admits of a moderate circulation of air, and yet prevents decided currents of air.

5. By it may be used corrosive sublimate, or other germicide, of sufficient strength to be certainly fatal to all germ life, without in the least degree endangering the patient, or being inconvenient or unpleasant to the operator or his assistants.

6. By it is utilized, condensed and reflected all the light to be obtained from window, the abdominal cavity being nicely lighted in all parts, so that the reflecting mirror is not a necessity, even when there is a poor supply of light, on account of a small window or a cloudy day.

7. Operator cannot by accident or intent witness patient's face, so that he is not in any manner disconcerted by the appearance of the patient.

[The cloth should be doubled between the operator and the patient's face.]

8. The assistant who administers the anæsthetics cannot witness the operation, and consequently will be less likely to forget his duty, namely, that of keeping steadily eye and mind upon the patient and effects of the anæsthetics.

9. By its use is prevented largely the circulation of the chloroform or ether-laden atmosphere over the open abdominal cavity. Both agents being highly volatile are cooling and drying in their effects upon the surface with which they come in contact, and both of these conditions are undesirable in laparotomy, the maintenance of warmth and moisture being essential to successful results.

10. It is light and compact, may be easily transported, and can be kept in readiness for use at all times.

11. It may be used to advantage conjointly when all other known antiseptic measures are applied.

12. By its proper application a good antiseptic compartment is furnished, even in a room where carpets, wall paper, etc., etc., are undisturbed, and in this particular especially recommends itself, its moist walls catching particles of dust and germ element which may be in the atmosphere, and the strong solution of corrosive sublimate which is used in moistening the cloth walls of the cabinet must be certainly fatal to germ life when coming in contact.

To further perfect this device, I propose supplying air to the patient, operator and assistants from (as a matter of convenience) the same window from whence is derived the light for operation, without opening the window and without changing in a noticeable degree the temperature of the room, although the outside temperature may be at zero or lower. The objects of the device are:

1. To furnish the patient (in the event of evidences of collapse from the effects of the anæsthetic,

or other cause) promptly an abundant supply of pure air, without changing the temperature of room, and thus proving detrimental to the patient by affecting the open abdomen and the exposed viscera.

The *second* object is to furnish to operator and assistants an abundance of pure air to breathe while they are working in an atmosphere with temperature of high degree, and which is trying and exhausting to operator and assistants, the latter sometimes failing you in the rendering of efficient service at a moment when you most need them. The patient, is supplied, by boring a hole into the lower lateral or lower transverse wide window sash, say three-fourths of an inch in diameter. Into this opening is placed a piece of metal pipe, and to this attached a piece of rubber tubing, which is carried along the floor to a point opposite the patient's head, when it is brought up and secured conveniently near the patient's head. This tube should have a shut-off valve near its end and to the end of tube should be attached a mouth-piece made of hard and soft rubber. This mouth-piece should have a set of valves inlet and outlet, to the outlet valve to be attached another tube identical with that attached to inlet valve. This main inlet and outlet tube can be made to supply and carry off the air for patient and the three assistants outside of the cabinet, and the three assistants and operator within cabinet are provided for in the same manner by a separate set of tubes. From the main tubes, inlet and outlet, are taken smaller tubes, and these of sufficient length to allow operator and assistants to move about with ease: to these small tubes are attached the mouth-pieces, with entrance and exit valves, and the mouthpieces held in place by rubber bands, or other suitable contrivance. The individual supply and exit tubes, are secured one upon either side of the head, in such a manner that they will not in any degree inconvenience the operator or assistants. The main inlet and exit tubes for operator and assistants must always enter from the top of cabinet. In cold weather the iron tube, which is secured in the window sash, and to which at its opposite end is attached the rubber tubing, should be at least eighteen inches in length, and a lamp placed under same to heat the metal tube, and thus warm the air; or a better, although more complicated, device may be used by having a small coil of pipe surrounded by hot water, and a thermometer kept in same, to indicate the temperature of air inhaled. The main exhaling tube is attached to the window sash in any manner most convenient. A convenient mode of attaching these tubes to the window will be found in taking a strip of wood, say four or six inches wide, made to slide one part into the other, similar to the patent window screens, so that it can be readily made to fit a wide or narrow window; this appliance to have the necessary attachments for all en-

trance or exit tubes. The same may be placed into the window, as is most convenient, by raising lower sash or dropping upper one.

204 East Main Street, Marshalltown, Ia.

DR. WELLER VAN HOOK, of Chicago: I would like to inform the gentleman that Dr. Prince, of Illinois, is now using in his daily clinics an apparatus by which he sterilizes all the air used in his operating room. Everything in the room is kept in a constant state of asepsis. The effectiveness of the process has been tested a number of times, he tells me, by introducing into the room slips of sterilized gelatine, and seeing whether colonies of germs would grow upon them or not.

I would suggest that a single layer of gauze, like that used in Dr. Getz' cabinet, is not sufficient in thickness to prevent the passage of micro-organisms through it. This might be attained by means of a spray kept playing on the gauze all the time.

No operating room will ever be made aseptic, however, for the reason that every operator carries with him, either in his nostrils or in his mouth, enough germs to poison the entire mass of humanity. The only reason that our patients are protected is because the germs are enclosed in masses of decaying food, and thus prevented from being carried into the wound. The atmosphere which is carried from the lungs in expiration is in a comparatively aseptic condition. This is due to the fact that the air has been made sterile by means of contact with the moist mucous membrane of the respiratory passages.

DR. GETZ remarked that he made provision for the sterilizing of air in his cabinet by means of tubes carrying air into the room from without. "I do not claim for it a perfectly sterilized condition, such as could be attained if the cabinet were stationary; but it must be remembered that this is intended to be carried around from place to place, and it is so constructed that it can be put up or removed within the space of a very few minutes. It is thus available for all manner of operations."

ALCOHOLIC INEBRIETY, AS RELATED TO RESPONSIBILITY, AND CRIMINAL JURISPRUDENCE.

Read in the Section on Medical Jurisprudence at the Thirty-ninth Annual Meeting of the American Medical Association, Cincinnati, May, 1888.

BY T. L. WRIGHT, M.D.,
OF BELLEFONTAINE, OHIO.

Researches relating to the effects of habitual drunkenness on the structure of the heart and blood-vessels; and the known connection which often exists between heart disease and insanity—

especially described by Dr. Wm. Julius Mickle in his recent Goulstonian lectures—open a door for investigating the influence of inebriety upon the mental and moral movements. That the heart is very likely to become dilated in the habitual drunkard, when its pulsations increase in frequency from seventy beats per minute, to at least eighty-five per minute as a stated thing, is apparent. For the latter figures represent an extra and unnatural labor imposed upon the heart of nearly eight millions of beats per year—a change of heart beat from thirty-six millions to forty-four millions, in round numbers per annum. And that the large arteries also must sympathize and suffer with the heart is evident, for they necessarily become enlarged, lax, and bagging, as their tonicity and elasticity are gradually weakened or destroyed by constant and violent stretching. Of course such a state of the circulation, at one time strained and over-wrought, at another powerless and creeping, but with a heart beat always rapid, favors the advent of melancholy moods, leading to despondency and suicidal insanity.

It is obviously impossible, in a brief paper, to go over the whole field of the mental and moral disabilities imposed by alcoholic indulgence. I will therefore omit further reference to the changes and diseases of the circulation as factors in the disturbance, or the destruction of the reasoning faculties, and confine myself to the moral and intellectual incapacities directly traceable to the toxic impression of alcohol upon the nervous system.

The anæsthetic, the benumbing, the paralyzing influence of alcohol upon the nervous system, and especially upon common sensation, always darkens knowledge and misleads the judgment. This follows from the fact that accurate perceptions are wholly dependent upon definite and normal sensations. When the senses are disturbed and impaired, perceptions are correspondingly disturbed and impaired; and they are unable to present to the mind facts as they truly are, as they really exist in the surroundings. The fine shadows, and uncertainties and doubts, which invariably attend all human transactions, escape the notice of a man who is intoxicated; and being unperceived by him, he imagines they do not exist. Every thing has, to his mind, the quality and energy of absolute demonstration. He never hesitates, never doubts. He is therefore a bad, as well as a dangerous witness in a court of justice, and particularly in criminal proceedings, where he is very likely to appear: bad from defective knowledge, and dangerous from a morbid positiveness in conviction and assertion. It seems probable, indeed, that a drunken witness testifying as to events observed while sober, is more trustworthy than a sober witness testifying as to events observed while intoxicated.

¹ See Address "On the Heart and Circulation of the Inebriate Classes," by Dr. B. W. Richardson, in Proceedings of the International Congress on Inebriety, p. 32. London, 1887.

The drunken man is always in a state of partial anæsthesia. Everybody dislikes the familiar approach of a person thoroughly intoxicated. The sense of feeling in such an individual is benumbed, and he seizes the person of any one near him in a rude and rough manner. His touch, or rather his grasp is painful because it is violent. The inebriate unconsciously exerts a considerable degree of force in his movements in order that he may be assured, or may feel that he really is in contact with persons or things exterior to him.

This imperfection in the sense of touch is one of the indications of partial paralysis in the nervous system at large. Indeed, the general insensibility of nerve arising from alcoholic influence will become apparent upon a very superficial investigation. The muscular sense is greatly obtunded, as is evinced by the staggering gait, the impeded articulation, the unfixed eye, and the distorted countenance. The senses of sight, of hearing, and even taste and smell, likewise show evidences of disturbed and restricted function in various forms of illusion, hallucination and incapacity. Partial paralysis depresses the ordinary senses without exception when they are brought under the dominion of alcoholic liquors.

Paralysis, in whatever degree it exists, withdraws function in a corresponding degree from the control of volition. No effort of the will can remove, to the slightest extent the incapacities of paralysis. Apparent exceptions simply indicate imperfect paralysis. In this respect the effects of alcohol differ from those of opium and chloral and tobacco. Weakness, debility, prostration respond in some measure to the calls of volition; paralysis does not. Hence, the responsibility of inebriety is modified and peculiar. It differs from the responsibility of common narcotism; and very often, indeed, it is less in degree.

The organic nervous system of the alcoholic inebriate is equally and similarly affected with his nervous organism elsewhere. The drunken man perishes from cold more readily than the sober man. For, not only does alcohol abstract oxygen from the blood corpuscles, and thus "slow" the ordinary physiological combustion of the body—but it benumbs and paralyzes the heat centres,² and sensibly hinders and weakens their functions. Here is the point where alcohol becomes a valuable therapeutical agent in reducing abnormal temperature in disease. "Alcohol lowers, opium raises temperature," says Dr. Norman Kerr in his recent work on inebriety. Alcohol paralyzes universally, opium does not.

The paralyzing property of alcohol is that through which it is enabled to masquerade in the

character of a food; a food indeed, which possesses in its own nature no single suspicion of nutriment; a food "in a certain sense" as it is described; in brief, a "waste-restraining food," whatever that may be. The inquiry arises: What are the achievements of such a food in building up and sustaining the physical organization? The answer appears to be this: When eggs, milk, beef, potatoes, etc., have constructed and nourished the human body, alcohol, by its paralyzing powers and properties, interferes with, and prevents the natural and physiological waste of the organism; and thus it keeps locked up in the system for a period of time longer than is natural, matters which otherwise would have been cast out as effete and poisonous. Audacious assumption will sometimes deceive the very elect; and although alcohol is compelled to take a dark and tortuous way to attain to the unsubstantial semblance of "food," yet the false pretense may, in thoughtless minds, rehabilitate somewhat, a reputation badly tattered.

Still these disabilities imposed upon the several senses, and upon the universal nervous powers through paralysis, do not fully measure the disasters brought upon the human capacities and potentialities by alcohol. These wrongs and injuries are, indeed, merely elementary; but being elementary and alphabetical, they are the keys to the interpretation of whole libraries of moral, and mental, and physical, and constitutional debasement and destruction.

It is impossible for a mind, when the senses are obscured and lifeless, to receive accurate knowledge of persons and things exterior to it. But if it were possible that such knowledge should by some means become the property of mind, still, universal paralysis of the brain (although limited in degree) would prevent the normal use of the reasoning faculties, and knowledge would become the basis of mistaken and perverted conclusions. Again: If, perchance, the reasoning faculties should act with precision and clearness, the coördinating centres of the brain would be incapacitated for analyzing the relative quality of convictions, and the moral activities would be found halting and repressed. Moreover: Even if the moral nature was not thus embarrassed, still, this same brain paralysis would dull those finer distinctions both as to conviction and duty which are essential to the formulation of proper and rational motive and choice—perplexing the will and precipitating an irrelevant and irrational conduct.

When the receptive faculties are in good order, it may be presumed that all other mental powers are probably in like order. I mean as a general rule, for I am not ignorant that moral insanity and imbecility of will are held by many to present independent features. On the other hand, if the receptive mental faculties are impeded, or modified, or insensible, it is presumed that most com-

² Dr. Isaac Ott places these centres: "1st, in front of, and beneath the corpus striatum; 2d, the parts on the median side of the nodus curiosus; 3d, the parts about Schiff's crying centre; 4th, the anterior end of the optic thalamus. These centres are exciting or inhibitory, according to the kind of impression sent into them by the peripheral nerve endings." They are inhibited by the paralysis of alcohol.

monly all the other faculties, both of mind and sensibility, are likewise defective and unreliable. Dr. T. D. Crothers has directed attention to a mental state sometimes found in the inebriate, which he has called alcoholic trance. If a person cannot see clearly, hear correctly, smell, taste and feel accurately, if indeed, he is in a condition of partial paralysis in his entire nervous system, he is very liable to lose his sense of personal identity, so far at least as to be oblivious to what transpires with relation to himself while in that state of impaired sensibility. For it is the unimpeded action of the senses, and the feeling of perfect concord amongst them—one with another—which give to a man the idea of his individual existence, his own, his personal identity. Now it is common for a person to say after recovering from intoxication, "I do not remember anything that occurred." While this may be false, it also may be true, for the reason based upon science, as well as upon experience, namely, the drunken man is in every instance partially paralyzed all through. He is thus very prone to lose his sense of personal identity, that is, his sense of relationship with events and things exterior to him. He must be liable to lose his right sense of relationship with other persons and other things, because, being partially paralyzed throughout his entire nervous organism, he has no just, and regular, and natural sense of anything whatever. In fact the identity of a person which is associated with the impeded nervous power of partial paralysis, is to all intents and purposes, the identity of some other, some imaginary person with whom when restored to its normal condition the mind can have no links or chains of association. Thus considerable modifications in the sensibilities may eventuate in modifications in the sense of relationship which the sound mind should sustain to all things else. Hence, though there may be a modified sense of personal identity incident to modified sensibility of nerve, this is not always recognized in memory when the mental powers resume their natural purity and perfection.

These degradations are inseparable from the use and influence of alcohol. They are totally incompatible with healthfulness of body, clearness of intellect, and strength and delicacy of morality.

The degenerations and disabilities placed upon the human organism by alcohol are of universal application and are practically of the same nature in all cases. Therefore from whatever position they are viewed they present the same appearances and conduct to the same conclusions. Examine, for example, the responsibilities of the inebriate from the standpoint of consciousness. Take the definition of Wundt, that consciousness is psychologically a unification, although itself a unit. According to this author, consciousness is not simply "a knowledge," or "function," or "condition." He tries to tell what it is, not what

it is for, or what it does. There is no nerve-centre of consciousness, and the entire organism is essential to its exposition. "Thus perception, representation, idea, feeling, volition, form the continuity called consciousness—of which only tautological definitions can be formulated. Taken as a whole, consciousness embraces the following movements: first, impression; second, transmission to a nerve-centre; third, general or vague perceptions; fourth, special perception (called also apperception); fifth, voluntary reaction; and sixth, transmission to the motor nerves." But all these elementary constituents of consciousness are benumbed, dulled, hindered, dwarfed in stature, repressed in function, and deranged in natural order of procession by the paralyzing influence of alcohol.

Not only is the rational faculty injured by the influence of alcohol, producing confused, incoherent, and inconsistent ideas and beliefs, but the moral attributes are debased in an equal degree. The paralysis of alcohol, although incomplete, fails not to overcome the finer and more etherial sensibilities, while it leaves the coarser ones comparatively unaffected. That is, it destroys the humanitarian sensibilities, leaving the purely animal ones nearly untouched. And this is, in effect, the suppression of the distinguishing characteristics of the human nature, and leaving in command the brutish and animal instincts, without check or monitor. What follows? The man does not wickedly and maliciously act *like* a brute, but he has become in reality a brute himself, through the loss or suppression of his humanizing sensibilities.

Latency of function is followed by difficulty, if not even impossibility, of function, through atrophy of structure. A curious exemplification of this principle is furnished by Dr. Livingstone, the famous traveler and philanthropist. He said that upon coming into the presence of his countrymen after years of absence among the black tribes of Africa, he was at home in everything except his own mother tongue. "I seemed to know the language perfectly, but the words I wanted would not come at my call."

Nothing is more common than that men, after drunkenness, are amazed at the shocking things they have done, or said, or thought, while in a state of intoxication—indicating the latent state of the moral nature in drunkenness. But if the inebriation is continuous or nearly so, that is, if it is habitual, the shocking thoughts do not become the subjects of rational review; and thus the latency of the moral sense becomes fixed, and congenial to an unsound and deformed reason. The mind may seem to know the nature of morality perfectly, but if morality is wanted, "it will not come at the call." It is therefore not surprising that steady drinking, even when not excessive, is more disastrous in the final outcome

than the convulsive sprees of the neurotic inebriate. In the latter, the intervening seasons of total abstinence prevent the establishment of habitual disability in the nervous powers; while in the habitual drunkard, nervous disabilities, latencies and inhibitions become perpetual, insurmountable, in a word, *constitutional*.

The chronic inebriate furnishes a ready and sure illustration of the foregoing facts and doctrines. He is debased and defective in every department of his nature. Physically, mentally, morally he is wounded, maimed, crippled, deformed, in equal degrees. Yet his moral deficiencies are the most obtrusive, because they lie most upon the surface. A gentleman of my acquaintance has been a steady drinker of ardent spirits for nearly thirty years. His moral nature is latent, if, indeed, he has any. He is not vicious or malignant, but he is an incessant and shameless, because motiveless, liar. With great coolness he will invent stories totally without foundation and on the most trifling subjects,—all the attendant circumstances and details being of the utmost exactness. And so he cackles on, and will continue so to do till the end of life.

Now this seems very foolish indeed, and likewise very inoffensive. But this man is, in truth, on the verge of insanity. Not only is he morally bankrupt, but his intellect is both sterile and disordered. Amongst the great army of the unrecognized insane there are none more common, or more really dangerous, than the chronic and steady drinkers of ardent spirits. These men in early life acquired the usual habits, both of thought and action, that belong to the average citizen. Automatically, with the guide and hints of the examples of others in their midst, they manage, without much effort, to keep in the ordinary grooves of daily life. If such a man is a farmer, by force of habit he farms as others do; and in a judicial inquiry, should that fact be established, it very likely determines nothing. If he is an artisan, or physician, or lawyer, he may, by automatism and example, pursue his avocation with reasonable success. But let some supreme crisis intervene, so as suddenly to throw him upon his own unaided powers; let instant rage or, what is more consonant with his nerve defect, jealousy, come over his mind and disposition, he will then be thrown out of the grooves of automatic life and, acting upon his own true nature, he will herald to the world his real condition. Then desperation, murder, suicide, true representatives of his actual mental state, will burst unexpectedly upon the scene. To the great body of chronic inebriates this crucial test of insanity is never applied; they live without recognition, and die with their dreadful infirmity unknown and unsuspected.

There is another large field of inquiry related to the jurisprudence of inebriety. It is that one opened by the property of alcohol which promotes

proliferation of the interstitial tissue. This field includes the whole organism, for the connective tissue goes everywhere. Dr. Sieveking asserts that "there is scarcely a degenerative condition of the body that may not result from the habitual use of ardent spirits."³ Dr. Maudsley speaks of that "more dangerous form of habitual indulgence in small quantities of wine and spirits throughout the day by which some active men of business endeavor to spur their overtaken energies."⁴ Alcoholic structural affections of the stomach, liver, kidneys and brain are familiar to all. They are invariably associated with physical changes in the connective tissue of the organism; and they originate from the persistent, the unremitting, the *habitual* influence of alcohol upon the bodily structure.

And this completes the tale of the essential departments of human nature—mind, soul, body. Each and every one is grievously and permanently disabled; and indeed wrecked, in the chronic inebriate.

THE EARLY REMOVAL OF ABDOMINAL CYSTIC TUMORS.

Read in the Section of Obstetrics and Gynecology, at the Thirty-ninth Annual Meeting of the American Medical Association, Cincinnati, May, 1888.

BY C. R. REED, M.D.,
OF MIDDLEPORT, OHIO.

By the term "cystic tumor" in this paper will be included tumors having their origin or growing from the uterus or its appendages, the bulk of the tumor chiefly fluid and contained in a cyst or sack; uni or multilocular, of the ovary, the parovarium, the broad ligament, or the Fallopian tube. It was formerly the teaching and practice of ovariologists that the removal of cystic tumors of the abdominal cavity should be delayed until they had produced emaciation, or the fat in the abdominal walls had been absorbed; the general health began to suffer; the vital organs become injured to irritation, and the long-continued pressure of the peritoneum had rendered it tolerant of irritation and less disposed to inflammation than when the tumor was removed at an earlier stage.

But the teaching of modern abdominal surgery is to remove the cystic tumor as soon as the diagnosis is clear, while the general health is unimpaired and the tumor is simple in character, has formed no adhesions to surrounding tissues and its contents have not undergone degeneration. While the tumor is yet small and free from complications, its contents thin and flow readily through the canula, but little time will be needed for its removal, and it is now the generally received opinion that the time consumed in the operation is in a direct ratio with its success. The

³ Life Assurance, p. 59 (1878).

⁴ Pathology of Mind, chap. ix, p. 434 (Appleton, 1880).

long continuance of the anæsthesia and exposure of the abdominal organs to the atmosphere render the shock more severe and of longer continuance, thereby largely increasing the death list of the operation. Under modern aseptic surgery shock is one of the chief causes of death in abdominal section, and whatever tends to lessen its severity or shorten its duration increases the ratio of recoveries. That cases recover after operation which had existed five, ten, or even twenty years are but exceptions to the rule.

American authors differ widely on this question of early or late operation for the removal of abdominal cystic tumors, while European authorities advocate the early removal. Goodell "*Lessons in Gynecology*," p. 362, says: "The operation should not be performed when the cyst has first been discovered, but when it has grown so large as to distend the belly, and when the woman has become thin and her health has begun to fail.

The abdominal wall having become thinner, the incision will be proportionally shorter and shallower; that the patient being now less full-blooded both hæmorrhage and inflammation will be less likely to occur, and that the pressure and rubbing to which the peritoneum has been for some time subjected will make it less vulnerable, and therefore less likely to take on inflammatory action."¹ If this theory be true, the operation in the well nourished should be preceded by a full venesection.

Emmet, in his "*Principles and Practice of Gynecology*," p. 711, referring to the doctrine of delay, as taught by Goodell and others, says: "But, on the other hand, the patient was deprived of all chances of recovery when the removal was delayed until the vital powers became so much depressed that she could not recover from the shock of the operation. With greater experience in the method employed it has already been demonstrated, as we shall see hereafter, that all the advantages are now greatly in favor of an early operation, before adhesions have been formed."

Sir Spencer Wells, in his late work on "*Abdominal Tumors*," in speaking of palliation by tapping, says: "But this advice as to tapping, and especially as to renewed tapping, as a means of cure must be restricted absolutely, as I have before stated, to cases in which the cyst is single and the contents clear and non-albuminous. In all cases of multilocular or dermoid tumors, where the abdominal distension is sufficient to injure the general health or cause local suffering, there must be no faltering, no suggestion of alternatives or delay. Justice to the patient demands a positive recommendation of excision, and generally it should be accompanied by a warning against the danger of delay. Every one who takes upon himself the responsibility of such counsel should

have a clear idea of the base on which it rests. And it may be traced out summarily in this form. The health has already deteriorated, and though the tumor itself be neither malignant, inflamed, or suppurating, nor the seat of hæmorrhage, yet its mere presence is the cause of the patient's decline. To let things go from bad to worse without doing anything, especially as that worse is a certainty, would be acting against the very first principles of medical science. The presence of this morbid growth in the body may give rise to other diseases. The contents too, whatever they may have been at first, alter in their character and become less and less benign, and by too long waiting sympathetic morbid action may be set up in the corresponding organ and thus make the ablation of both imperative. Time, too, gives the opportunity for adhesions to form, for rupture or destructive peritonitis to occur. It is possible to operate too early as well as too late, to place a person's life in peril by operation before it is endangered by disease, just as it is possible, on the other hand, to delay operation until the powers of life are so exhausted that recovery after a severe operation is impossible. He further says that ordinary medical treatment by drastic purgatives and hydrogogues often do harm, and rarely good, and any specific medical treatment by iodine or bromine, or mercury, or gold, or, arsenic, or lime or potash, used with the hope of checking the growth of such tumors, is useless, and he further says: "I have become more and more disposed to advise the removal of an ovarian tumor as soon as its nature and connections can be clearly ascertained and it is beginning physically or mentally to do harm, since the risk of the operation under such circumstances is certainly less, and the possible evils of delay are eluded."

Sir James Y. Simpson, in speaking of the treatment of abdominal tumors, says: "He had no belief whatever that iodine, or mercury, or muriate of lime, or aqua potassa, or diuretics, or deobstruents, or aught else, was capable of absorbing and removing the complicated structure and contents of a multilocular cystic tumor of the ovary."

Matthews Duncan says: "We know of no one example of the cure otherwise than by the operation of Ephraim McDowell, of an ovarian dropsy, properly so called. Not one, however many may be found described, or whoever may be the describer. Cures by one or moreappings, cures by medicines, cures by spontaneous rupture, cures by advancing pregnancy have been, if not most egregious mistakes, almost certainly cures of parovarian cysts, whose history, as already known, quite accords with and explains such erroneous allegations."

Mr. Lawson Tait, in his late work on "*Pathology and Treatment of Diseases of the Ovaries*," pages 252 and 253, says: "The treatment of ova-

¹ Dr. Goodell, in the 2d edition of his work, corrects his statement as quoted above.

rian tumors by therapeutics need not be discussed, further than to say that it is limited to the administration of tonics to sustain the functions of the patient, or to correct some errant condition which might diminish the chances of success for the surgical treatment of the case. For the cure of an ovarian cystoma there is nothing known to have the slightest influence, save an operation for its removal, and those patients who unfortunately are led to believe that some drug or other, or some fanciful form of treatment will relieve them from the necessity of an operative ordeal, are only induced to waste time which is valuable and to run risks which may be avoided. Of tapping I have said as much as I think necessary, but here I may repeat what everyone knows now, that it never cures a tumor and that it only brings about complications. It is my firm belief that if ovarian and parovarian tumors were never tapped, but were removed early in their history, we should only have a casual mortality from the operation of ovariectomy. Tapping, therefore, in my practice has become only a palliation for tumors I could not remove.

Many other plans have been devised for the radical cure of ovarian tumors, but they are all now abandoned in favor of ovariectomy; and such methods of treatment as the injections of iodine, or the establishment of fistulous tracks, can only be justified under very exceptional circumstances. Before the re-introduction of the intra-peritoneal method (of treating the pedicle) by Dr. Keith, we used to delay the removal of an ovarian tumor as long as the patient could get about comfortably, and this was justified by the fact that with the clamp we got only about 75 per cent. of recoveries. But now that we can get 95, and when we might get 99 per cent. of recoveries, if there were no delayed or tapped cases, my rule is to remove an ovarian tumor as soon as it is discovered, and this will soon come to be the received practice. The earlier the operation is performed the more certain the patient is to recover, for the less likely are there to be any complications." Tait further says: "However advanced a case may be I never refuse to operate, for I have seen some of the most unpromising cases recover without interruptions."

I have quoted at some length from Sir Spencer Wells, Lawson Tait, and others, as their statements are corroborated by the following cases, with others that might be detailed, coming under our observation.

Case 1.—Mrs. S., aged 36, mother of several children, first noticed an enlargement or tumor of left ovarian region about January 1st, 1875. The tumor was of slow growth the first three or four months, then grew rapidly, when the pressure becoming great and refusing an operation for removal she was tapped June 23d, 1875, about seven months after the tumor was first noticed. The relief was entire for three months when the cyst

rapidly refilled. On October 7th she was again tapped, under protest, with relief for six weeks. The cyst then rapidly refilled, and tapping was again done November 29th, with but partial relief. The fluid removed the first two tapplings was thin and albuminous, now became thick, flocculent and purulent. She was now rapidly failing in nutrition and strength, and suffering severe pain in abdomen. On December 13th, fifteen days after last tapping, the fluid was again removed by trocar with much obstruction in flowing through the canula. It now became evident that each tapping prostrated her more, nausea and vomiting becoming frequent and the end rapidly approaching, and as we refused to tap her again, she and her friends consented to removal of the tumor, and about the 20th of December she was seen by Dr. Dunlap, of Springfield, Ohio. Dr. D. tapped her with a large aspirator, hoping that by again emptying the cyst she would recuperate sufficiently to undergo the operation of removal. She continued much the same, and on January 6th, 1876, the tumor was removed by Dr. D., Mrs. S. dying from shock one hour after the operation.

The tumor was a unilocular cyst without complications or adhesions and easily removed. We believe that had Mrs. S., and friends, consented to an early operation, while health and strength were good, she would have survived the operation, and that she was the victim of delay. The temporary relief usually following a first tapping deceives the patient and friends and leads them to believe that its occasional repetition will indefinitely prolong life. Of this deception she and her friends should be warned.

Case 2.—Miss S., aged 16, commenced menstrual life at 13, one year after which she observed an enlargement of the lower abdomen. This growth we are told slowly increased the first year, the general health suffering but little. The second year rapid development and failing in health and strength, though able to walk about. The tumor now so large as to displace the abdominal organs and greatly increase the circumference of the chest. Menstruation, heretofore irregular, now ceased. Her treatment was wholly medicinal, and no doubt an injury rather than a benefit to her. A consultation now resulted in a diagnosis of ovarian cyst, and its removal recommended and positively declined. She persistently refused an operation for relief, and rapidly became more emaciated and anæmic, nausea and vomiting and loss of appetite now became prominent symptoms. When we saw her first, November 2d, 1887, and diagnosed a large cystoma which was rapidly destroying life, and the end was near. We objected to any further medication and told her her only hope was in the removal of the growth which we did on the 5th of November. She bore the ether badly, vomited frequently during its administration, and also during the operation, which neces-

sarily prolonged it. The abdominal walls were free from fat and very thin, which made the tumor readily accessible, which was found to consist of three large cysts and several smaller ones, the walls of each thick and tough, and contents of each unlike. The large cyst in front and below was filled with thin fluid and readily emptied; the second with colloid contents and slowly flowed through the canula; the third had adhesions to the abdominal wall posteriorly, and contents so thick and dense that they would not flow through the tube and the wall had to be punctured with the scalpel and the semi-solid contents scooped out with the hand. The adhesions were broken up with the hand, the emptied cyst walls were brought through the incision. The tumor was found to grow from the left broad ligament, with a long, broad pedicle, which was tied with the Staffordshire knot.

The difficulty in evacuating the two latter cysts made the operation a long one. There was no hæmorrhage requiring ligature, the condition was one of anæmia. The abdominal organs were forced, by pressure, from their normal positions and did not occupy that place when the tumor was removed. The uterus and ovaries were small and healthy and were not disturbed. At the close of the operation the radial pulse was barely perceptible. The shock was great. After the anæsthesia passed off there were indications that she might rally, but she died two hours after the operation.

There is nothing unique or unusual about the above cases; they are given in detail as we think they teach a lesson. The life of the young girl was a sacrifice to her fear and dread of an operative ordeal. They teach us the utter inefficiency of a cure by medication; that the removal of the cystic tumor is her only hope and safety; that tapping is but temporary relief, a false hope, and complicates removal as a means of cure. The woman who has an abdominal cystic tumor should be told by the physician that its early removal while it is small and free from complications is almost free from danger, and warned of the danger of delay. Then will cystotomy be shorn of its terrors and the per cent. of recoveries in this country nearer approach that of Great Britain and Continental operators. Other cases have been seen by us that have been tapped again and again, and died. Others have passed away without even this temporary relief, and successful cases coming under our observation, operated on early, are not detailed here as they would be void of interest and extend this paper beyond its intended limits.

May, 1888.

RETINITIS HÆMORRHAGICA FOLLOWED BY GLAUCOMA.

BY KENT K. WHEELOCK, M.D.,
PROFESSOR OF OPHTHALMOLOGY AND OTOTOLOGY IN THE
FT. WAYNE COLLEGE OF MEDICINE.

March 19, 1888, Mrs. Esther Smith, æt. 71 years, widow, consulted me on account of an eye trouble. She stated that her vision had been somewhat obscured in her left eye for a few days, and that at the time of her visit she was quite unable to distinguish objects on account of everything being clothed in a deep purple color. Upon examination I found R.E.V. = $\frac{2}{3}$ %; + 1D. V. = $\frac{2}{3}$ %. L. E. V. = perception of form.

Ophthalmoscopic examination showed a large number of circular red spots in all parts of the fundus, macula especially presenting the appearance as seen in embolism of central artery of retina, except the hæmorrhage was not defined, but shaded off into other hæmorrhages. Tension normal. Patient well preserved, and gave no evidence of heart changes or vascular degenerations which I could detect. Fundus and vitreous hazy in certain strata. I prescribed sol. muriate of pilocarpine one-fourth per cent., teaspoonful to be taken every hour till sweating was induced. This was followed by amelioration of the distressing chromatic changes and by improvement of the vision, so that fingers could be counted in the temporal field. Pot. iodide was then ordered, with ung. hydrargyri, lanoline as a base, rubbed over brow and temple. No especial change occurred subjectively beyond the gradual fading out of the purple color which before surrounded all objects. Objectively the hæmorrhagic spots faded and brightened with the usual persistency.

Finally, about the middle of May, tension began to increase slightly and a pinkish red blush stole over the sclerotic and circumcorneal area. Eserine was promptly applied, but acted badly. I advised operative procedure, but the patient was timid and could not consent.

On June 20, after an unusually bad night and intense circumorbital pain, the patient consented to an operation. Having grave doubts as to the success of any operative interference save enucleation, which the patient would not consent to except as a last resort, and fearing the possible extrusion of the ciliary body, vitreous, etc., if an iridectomy were done, by reason of sudden relief of the corneal counter-pressure, I elected to do a sclerotomy. As long as there was a fistulous opening in the line of the incision, which was not completed above, a small bridge being left for support, pain was not experienced. When this fistula closed the trouble returned with increased force, and the pain was less bearable by reason of the patient being reduced in nervous force. Seven days after the sclerotomy it was evident that another operation must follow. Seeing no evidence

THE BERLIN SEWAGE FARMS now yield a profit of two per cent. on the capital invested—a very favorable result, considering all things.

of undue pressure from behind following the sclerotomy, I did a large iridectomy downwards. Patient experienced complete relief of pain, and now, nearly three weeks after the operation, the eyeball is soft and has regained its normal appearance.

Pt. Wayne, Ind., July 16, 1888.

ABSTRACT OF PAPER ON THE HISTORY AND TRUE VALUE OF THOSE AIDS TO HEARING USU- ALLY TERMED ARTIFICIAL TYMPANIC MEMBRANES.

*Read before the Section of Otology of the British Medical Association,
August 10, 1888.*

BY LAWRENCE TURNBULL, M.D., PH.G.,
AURAL SURGEON TO THE JEFFERSON MEDICAL COLLEGE HOSPITAL,
ETC., PHILADELPHIA, PA.

I have endeavored to give a full history of the use and application of the various agents employed in the place of the natural membrana tympani. By this time we have arrived at some certain definite ideas as to the true value of these aids to hearing:

First, their importance to the health of the ear, by preventing dryness, and the general danger to the hearing from the want of the protecting power of the natural membrane.

Second, we can hear to a certain degree without the membrana tympani; but we cannot have perfect hearing without it.

Third, we have in the various agencies which have been employed not only the means of protecting and preventing the drying effects of the air, but also the prevention of the passage into the middle ear of injurious foreign agents, the prevention of disease from cold air or water, so apt to set up acute inflammation, followed by abscess in the mastoid or brain.

There are certain agents that we have individually found to perform the offices we have described, with the least injury to the ear, and still retain bone contact, make a certain amount of pressure, protect diseased parts and tend to the healing of the perforation. Satisfactory results have been obtained from the cotton ball, or pellets of "Yearsley." The objection to this was the tendency, which the ordinary cotton had to cause irritation, by bearing in its fibres bacteria and micrococci, also other foreign matters. Again, it sometimes fits so closely, owing to discharge or mucus on its surface, as to make a shut sac, and absolutely prevent the vibrations of the membrane, thus acting as a damper. These difficulties are overcome by employing corrosive sublimate solutions with "sublimate cotton," or a disk of sublimate gauze, moistened with fluid cosmoline, so as to make it more adhesive. When water with glycerine is employed the mixture will soon ferment in the ear and become irri-

tating, and causes inflammation. By treatment we can much sooner employ the artificial membrane, even when there is a slight suppurative process going on. The solution of the sublimate should not exceed in strength, one to four thousand, if stronger it gives pain. The patient is supplied with a dozen or two of these cotton pellets, attached to threads which have also been soaked in the solution. The fluid cosmoline or vaseline is to moisten the pellet, when about to be introduced if the parts are dry. The pellets are placed in position by means of the ordinary forceps, called tweezers, such as are found in every lady's work-basket, the thread must be cut off close, so as not to be seen. The second form is the india-rubber disk, cut out with the apparatus of Gruber, and introduced with the forceps, as seen illustrated in the writer's work.¹

We have discarded all the forms of apparatus which have any metallic spring, handle, etc., having found them always irritating and injurious, even our own modification, the stem of which we had carefully covered with rubber. We find the rubber curls up, and is destroyed, leaving the metal exposed.

We apply a disk of what is known in this country, as "Mead's adhesive plaster," which is found to be perfectly pliable and antiseptic, or the same make of "boric-acid-plaster." Its mode of use and report of cases, will be found in the writer's work, p. 491. Even since the issue of the last edition, 1887, we have had reports from almost every case of its success in relieving deafness, assisting the perforation in closing, the plaster being retained for months, and in one case two years, with but little irritation.

Dr. C. M. Thomas, of this City, informs me that he has found the "oil-silk," such as is employed in antiseptic dressing, a very successful artificial membrane, looking and acting like the natural one. He cuts them the size required, leaving a small opening in the center. In some two cases he has found the hearing of the patient much improved even after their removal. Dr. C. S. Turnbull, my son, also of this City, employs with success, a pledget of antiseptic wool placed near to, but external to, the annulus tympanicus.

MEDICAL PROGRESS.

TRANSPLANTATION OF MUCOUS GRAFTS.—At the meeting of the XVII Congress of German Surgeons WÖLFLE, of Gratz, read a paper on this subject. He restores the continuity of the mucous membranes after excision of neoplasms or cicatrices by transplanting strips of mucous membranes to the uncovered places. The grafts were

¹ Clinical Manual of Diseases of the Ear, 2d ed., 1887, p. 489. J. B. Lippincott & Co., Philadelphia.

at first taken from the uterus or rectum of persons suffering from prolapse, or from the cervix of amputated uteri. Later he used the mucous membrane of animals (the stomach of the frog, œsophagus of rabbits and pigeons, vesical mucous membrane of rabbits, etc.), though his experiments in this direction are not completed. The mucous membrane was excised by the method given by Thiersch for epidermal grafts, or simply separated from the muscular layer of the viscera. He found that mucous membrane adheres as firmly as the epidermis. The permanence of transplanted mucous grafts was clearly demonstrated in a case of urethral stricture in which the continuity of the canal was determined at the autopsy, six months after the transplantation. Three cases of urethral stricture treated by this method are reported. The mucous grafts were taken from the prolapsed uteri of two females. The urethral cicatrix was completely excised, and the granulating surface covered with mucous membrane after Thiersch's method. No suture was required, but the surface was protected by a strip of iodoform smeared on its inner side with vaseline. The dressing was removed in from three to four days when a grayish sticky mass was found beneath. In three more days the granulating surface appeared as if covered with a film of mucus, and at the lapse of an equal period, the granulation tissue was seen to be replaced by a smooth glistening layer of perfectly formed mucous membrane. Equally successful results were obtained in blepharoplasty and rhinoplasty, the mucous membrane being taken from the prolapsed rectum of a child and from an amputated cervix uteri. In a case of rhinoplasty of the cheek the author successfully employed mucous membrane from the œsophagus and stomach of a rabbit.

In the discussion of the paper Prof. Thiersch stated that Wölfler's method was an important advance in surgical technique. He took exception, however, to the statement that implanted tissues assumed the character of the structures in which they were implanted, and cited his case of a man who, after transplantation of a skin flap from the cheek to the soft palate, found it necessary to shave the inside of his mouth on account of the growth of hair over the transplanted area.—*Berlin, klin. Wochenschr.*, No. 17, 1888.

DEAFNESS AS THE RESULT OF SYPHILIS.—At the close of a paper on this subject, DR. LAWRENCE TURNBULL draws the following conclusions:

First. That syphilitic diseases of the ear are less numerous in the United States than in Great Britain or Europe, and that it is not so frequently a cause of deaf mutism.

Second. In almost all constitutional syphilitic diseases of the ear in children and young persons

it is associated with some affections of the eyes, throat and nose. The deafness which often follows the improvement in the eyes is sometimes profound.

Third. Persons who have suffered from constitutional syphilis, especially young persons and children, have great impairment of conduction of sounds through the bones of the head. Even in adults with constitutional syphilis the tuning-fork in some instances cannot be heard on the bones of the head or face.

Fourth. In a few cases the first indication of a syphilitic diseased ear is a primary ulcer in the throat, naso-pharyngeal space, or in the auditory canal, or near the membrana tympani.

Fifth. Purulent otitis media, or otitis media serosa syphilitica, may occur in utero, or in very young infants, while in young persons and adults we may have congestion of the tympanic mucous membrane from the same cause, ankylosis of the bones of the ear, with bands of adhesion in the middle ear, by extension from the throat to the Eustachian tubes.

Sixth. Syphilitic disease may affect the most vital part of the internal ear, labyrinth, semi-circular canals and cochlea, with hyperæmia, marked thickening and dryness of the membranes of the round and oval windows and vessels which supply the internal ear. There is also disease of syphilitic nature in the auditory nerve, also the brain itself, in the formation of disseminated small nodules within the nerve centres. This form of disease of the ear is most successfully treated by the combined use of pilocarpin and mercury.¹ Another valuable preparation in obscure syphilitic cases is the following:

R	Hydr. bichlor.	gr. $\frac{1}{3}$
	Acid. arsen.	gr. $\frac{1}{4}$
	Ferri pyrophosphat.	gr. vj
℞	Divide in pil. No. xxiv.	S.—One three times a day.

Care must be exercised in the use of powerful drugs, as there have been cases of jaborandi and pilocarpin poisoning. Two cases have been reported of poisoning: one from two drachms of the fluid extract of jaborandi (which required no antidote), and the other from swallowing a considerable dose of the fluid solution of pilocarpin used for stimulating the hair, instead of a solution of quinine. In both cases the symptoms were profuse perspiration and salivation, dimness of sight, prostration, a sensation of cold tremor and extreme general debility. The treatment of the pilocarpin case was with atropine, which is the antidote.—*Phil. Med. Times*, Sept. 1, 1888.

ASPIRATION IN SUPPURATIVE PERICARDITIS.—DR. EDWIN T. DOUBLEDAY reports a case treated by aspiration, and calls special attention: *First*,

¹ See p. 496, Author's "Manual of Diseases of Ear," for full account of cases.

to the fact that the patient never had any symptoms either of rheumatism or nephritis. *Secondly*, that the pericarditis was probably idiopathic. *Thirdly*, to the almost entire absence of fever while the case was under observation. *Fourthly*, to the large amount of pus withdrawn at one time, 51 ozs. *Fifthly*, to the fact that over 17 pints of pus were withdrawn from the pericardium in thirty-four days' time. As showing the effort that nature makes to cure these cases, I may cite one mentioned by Wyss, in which there was a pyopericarditis followed by the formation of a fistula lasting for years. The patient finally died of an attack of acute pericarditis.

I believe that in cases of pericarditis where there is a distant and muffled heart-sound, with a weak and rapid pulse and dyspnoea, an exploratory puncture with a hypodermic needle should be performed; that, if pus is present, the pericardium should be thoroughly aspirated; and that if, after two aspirations, the pus reaccumulates, an operation should be performed to establish drainage, and the cavity be washed out, if this be deemed expedient. Of course, in aspirating, the physician must take the risk of converting a serous into a purulent inflammation, as sometimes takes place in cases of pleurisy, even when the best antiseptic precautions are taken.

In cases in which drainage or washing out of the pericardium is employed, I think it would be well to prevent the pressure of the air upon the heart, as in fourteen cases of pneumopericardium, ten died from either sudden heart failure or asphyxia: This might easily be done by the use of a rubber bulb, with a valve opening outward, on the end of the drainage-tube, or by keeping an aspirator attached to the end of the tube and by occasionally turning the ratchet, so as to keep up a slight vacuum.—*N. Y. Med. Journal*, September 1, 1888.

THE PROPER TIME FOR THE ADMINISTRATION OF ACIDS, ALKALIES, ETC.—Alkalies should be given before food. Iodine and iodides should be given on an empty stomach, when they rapidly diffuse into the blood. If given during digestion, the acids and starch alter and weaken their action. Acids, as a rule, should be given between the digestive acts, because the mucous membrane of the stomach is in a favorable condition for the diffusion of the acid into the blood. Acids may be given before food when prescribed to check the excessive formation of the acids of the gastric juice. By giving it before meals, you check the osmosis stomach-ward of the acid-forming materials. Irritating and dangerous drugs should be given directly after food, such as the salts of arsenic, copper, zinc, and iron, except where local conditions require their administration in small doses before food. Oxide and nitrate of silver should be given after the process of digestion has

ended; if given during food, chemical reactions destroy or impair their special attributes, and defeat the object for which they were prescribed. Metallic salts, especially corrosive sublimate, also tannin and pure alcohol, impair the digestive power of the active principle of the gastric juice, so should appear in the stomach during its period of inactivity. Malt extracts, cod-liver oil, phosphates, etc., should be given with or directly after food, so that they enter the blood with the products of digestion.—*British Medical Journal; Dietetic Gazette*, July, 1888.

RECOVERY AFTER RUPTURE OF THE FALLOPIAN TUBE.—DR. DUCHAMP, of Lyons, records in the *Lyon Médicale* the case of a woman who had menstruated on April 30, and was suddenly attacked on June 17 with syncope, vomiting, and a feeling of something having given way in her abdomen. He was called in consultation on the following day, and found her in a condition of collapse. The pulse was almost imperceptible, the abdomen much distended, and extremely tender in the umbilical region. The patient was vomiting greenish matter. She stated that the pains had commenced just above the pubic region, and were accompanied for about half an hour by vesical tenesmus. Vaginal examination disclosed nothing definite. An intra-peritoneal pelvic hæmorrhage was suspected, and on the afternoon of the same day Duchamp performed laparotomy, after previous catheterization and thorough disinfection of the abdomen. A spray was not used. The abdominal cavity contained a quantity of fluid and clotted blood, of which 2.5 liters were evacuated, and a fœtus, about 2 cm. long, extracted. Old peritoneal adhesions were found and a perforation of the left tube. The tube and ovarian ligament was tied with carbolized silk, at two places close to the uterus, and the remaining part of the tube and the ovary excised. Three weeks after the operation the patient was discharged cured.

TREATMENT OF LEPRO.—BIDENKAP has seen but one case of leprosy benefited by Unna's ammonium sulpho-ichthyolicum out of many on which it was tried, and according to his observation the following is the best formula for local treatment. It is spread thick, and applied for thirty-six to forty-eight hours, every eight to fourteen days:

R	Olei Olivarum	20 pts.
	Resinæ Colophonii	20 "
	Cereæ flavæ	40 "

Melt over a water bath for half an hour, with constant stirring. Cool and add the following mixture:

R	Gummi resinæ ammoniaci	2 pts.
	Balsami Terebinth, venetæ	2 "
	Chrysarobini	12 "

THE PHYSICIAN AS A "NATURALIST."

That the physician should be a man of culture, of broad education, trained in mental discipline, and something more than a person whose business it is to visit sick people will some day be a truism—a truth appreciated by all. "The Physician as a 'Naturalist,'" was the subject of the Presidential Address of DR. WILLIAM T. GAIRDNER, of Glasgow, at the recent annual meeting of the British Medical Association. The subject is a deep one, and was most admirably treated, as was to be expected from the learned author.

Students of the history of medicine will naturally recall the fact that the educated physician was first a naturalist, a man of science—as science was at that time. Dr. Gairdner's argument was that for a series of indeterminable ages, probably from the time of Hippocrates down to the Dark or Middle Ages, the tradition has constantly existed that the *healer* or physician of the highest class should also be, in a very real sense of the word, a *naturalist*, or perhaps a man of science (physical science being of course understood); that it is his prerogative to be trained and exercised after the best manner and according to the most thorough discipline of the science of his age; and that he should be regarded as being admirable and trustworthy as a healer or physician, chiefly in proportion to the confidence reposed in him as a *naturalist*—an humble, reverent, and exact follower and student of Nature. To

be a student and follower of nature, one must study nature herself; to be an *exact* follower, one must be trained in and have exact and scientific methods of thought and work. Turning again to the history of medicine, we find that the immortals of the profession—and of all the physical sciences—were naturalists in being students and exact followers of nature. Such was Hippocrates—at least to the extent of the light that he had—and whom Galen places in advance of Aristotle, and far above the Peripatetics and the Alexandrian Erasistratus, whose attitude towards Nature was inconsistent. We see Bacon opening his *Novum Organum* by ascribing to man the position of minister or servant and interpreter of nature—the idea being very likely borrowed from Hippocrates.

It is unnecessary to refer to the causes of the medical obscurantism of the Middle Ages. Superstition and "magike naturel" ran riot, and were not without effect on medicine. The physicians of this time were learned, but not scientific. Even at the beginning of the last century, when science began to awaken from its long sleep, the man of learning—of the type of Linacre—greatly overshadowed the man of science—such as Harvey—in the Royal College of Physicians of London; and Oxford and Cambridge, the portals, one may say, of the College, had no standing at all as scientific schools, and confined their teaching to a mediæval curriculum, as do practically many of our schools to-day. And, indeed, at one period of the evolution of medical education in Great Britain, the true physician, the minister, student and follower of Nature, says Dr. Gairdner, stood a very fair chance of being altogether suppressed and wiped out of existence. Before Linacre obtained the charter of the Royal College of Physicians from Henry VIII, in 1518, the practice of physic was chiefly engrossed by illiterate monks and empirics, and the licensing power was held by the bishops in their dioceses. Possibly the officious meddlesomeness of some churchmen with matters medical, and their readiness to endorse so many things that savor of empiricism and quackery, may be the result of a direct spiritual inheritance from the old English bishops.

So far as Great Britain is concerned, the departure from the time-honored medical course without the sciences had its origin in the Scottish Universities, under Cullen, Black and Hope, who

forced chemistry into the medical courses, and thus the way was prepared for the introduction of botany, natural philosophy and zoology. And why not? One must have but limited powers of observation, and still more limited powers of accurate thinking, that does not acknowledge that the proper study of these sciences is conducive to an accurate mode of reasoning and observation. As Graves said: "The charge of inexperience is not necessarily confined to the beginner; it applies equally to many an old practitioner, whose errors have grown and increased in strength during a long series of years, because, from defects in his original education, from the absence of a properly directed clinical instruction, he commenced practice without having previously acquired the habit or power of accurate observation." One wholly untrained in scientific methods of observation is about as likely to reason correctly in regard to a scientific matter, and about as like to stumble accidentally upon a scientific discovery, as he is to fall to the top of a church steeple. In order to see and observe one must know how to look, and look until he sees. Give an untrained person a piece of blende and a piece of quartz; he may see no difference. How is he to find out the difference? Make him look until he sees. The naturalist must first know how to see what he looks at. He must have the power of attention; he must be able to observe correctly; then he will be able to reason accurately. The true physician, as a naturalist, must possess the same powers; otherwise he will see and observe only a part of what he looks at, and reason inaccurately.

What is still wanting to bring about the professional idea of the physician's training, is a question discussed by Dr. Gairdner. He has considerable personal interest in this subject, because he has a son to educate. "The first thing to be learned in order to make all other lessons possible is, in my opinion, this—to deal very largely with things and not with mere words; to realize as much as you can all your instruction by making it your own through personal observation; to suffer nothing, if it can possibly be avoided, to lie in the mind as a dead weight of vocables, oppressing the memory and dwarfing the intellect; but to bring everything into the living light of fact and of Nature, and thereby at once to assure to yourself the truth and exactness

of your knowledge, while at the same time you are stamping it down upon the memory by the most sure and lasting of all technical methods." These words, delivered by Dr. Gairdner in an address more than twenty years ago, are a text for all that can be said on the subject of the best training for the physician, the scientist, the man. No one hope or fear that the physician educated on scientific lines can compete with the scientist, the *physicus*, on his own ground; but we can reasonably ask and hope that "he should be open to the influences, and should work in the spirit, and be subject to the corrections of the more exact sciences, in so far as they are applicable to the human body, whether in its sound or in its pathological condition."

And yet it must be acknowledged that there are very great difficulties in the way of training students of medicine on the lines indicated, the first and chief of which is the want of *early* training in physics and natural science. We see students entering medical colleges with their memories weighted down by chemical and physical laws and formulæ, and *knowing* no chemistry and no physics. To teach them these subjects one must undo years of bad teaching or no teaching, and begin with the youth of 20 what should have been begun with the boy five or eight years ago. Perhaps after we have learned on this side the Atlantic *how* to begin to teach the sciences, we will begin to *teach* them. That day will come, because it must come; and when it does, the day of the now orthodox curriculum will have set. The true physician is a Naturalist, and must be educated as such.

COMPETITION, SUPPLY AND DEMAND, AND MEDICAL EDUCATION.

Just as soon as any one remarks on the surplus of medical colleges and the excessive production of physicians by the colleges in this country, another person assumes an air of superior wisdom and importance and replies: "Competition is the life of trade;" or "Supply and demand regulate the whole matter."

Wholesome competition is the life of trade; unrestricted competition may be the death of it. There may be such a condition of overcrowding of the profession as will tend to the production or increase of quackery, and to lower the

moral tone of physicians. Wholesome competition is the life of *trade*; but competition does not make or increase the business of the physician. We may admit that incompetent physicians make work for those that are competent. Unwholesome competition tends only to make the morally loosely-inclined physician worse; but it does not make the conscientious physician better, or more careful, or more scientific.

Some weeks ago a writer in a medical journal in this country gravely asserted, and perhaps believed, that it was useless to continue to speak of the bad work of some of the medical colleges, and of the large annual output of graduates—that the whole matter was one of supply and demand. The law of supply and demand has nothing to do with the matter, either of the number of colleges or of the output of graduates, nor can it have, for the reason that the public does not purchase its supply of physicians from the manufacturers (the colleges). The production of wheat, and its price, are regulated by supply and demand. The American wheat-grower gathers his in, and may sell it in July or August; he may even contract to sell a certain amount of it before it is reaped; or he may wait for better prices, and hold it until next May, according to the price, *regulated by the surplus*. If the medical colleges could go into the market and offer a certain number of first-grade graduates at a certain price, and as many slightly damaged graduates at a lower price, for cash, as if they were wheat or shoes, with a certainty of profit if there were buyers, and a certainty of loss if they were not sold or had to be carried over for six or nine months, then demand would regulate supply and quality.

But such is not the case. The student entering a medical college does not stop to consider if there is a place to be filled by him two or three years hence. He pays his fees to the college, goes through the course, gets his diploma, and his connection with the college ceases; and in so far as his finding a position is concerned, the college takes no further interest in him. Beyond a kind of sentimental interest in the graduate, the college is regardless of what becomes of him, unless he can occasionally send a student to it.

There are circumstances when demand may vitiate supply. If there be excessive demand and limited supply, the manufacturer is induced by cupidity to put out an inferior article, because it

can be made quicker and at less cost. Again, with small demand and large supply (output), the manufacturer has to put out an inferior article so as to underbid competitors. In the case of the medical colleges for which there is no demand (no proper and good reason for existence), they must, in order to exist, underbid the other colleges, either by lower fees, or shorter courses and terms of study, or less rigid requirements for entrance and for graduation, or all of these. Now as concerns students that are attracted by such inducements as these, the profession does not want them in it, and the public are better off by having them out of the profession. They are the men, as a rule, that furnish the failures in the profession; they go into it with the idea that it is a trade, thinking that if it does not suit them they can go into some other business. Entering the profession with these notions, they never get to the point of seeing anything in it except drudgery and dollars; if they make enough dollars to supply the necessities of life, they add nothing to the profession, and lower it in the estimation of at least some of the public. They are an incubus to the profession while they stay in it, and a good riddance when they drop out.

When supply and demand regulate the schools and the graduates, we shall confidently expect the free-agency of shoes to regulate their size and price.

"THE PARLOR-GAME CURE."

Every one admits the value of recreation for the healthy and well man, whether that recreation take the form of sport, travel, or simply a change of occupation. Recreation by one that is not sick is in the nature of prevention. In the *Popular Science Monthly*, for August, REV. THOMAS HILL, Ex-President of Harvard, has an interesting article on "the Parlor-Game Cure," or in-door recreation, which may of course be as varied as recreation in the open air, and one is not always able, and does not always care to go out of doors for relaxation and amusement. One may rest his mind and body by reading. If his early training has been in the direction of the more solid subjects and severer studies, he may find as much recreation in reading a work in some department of science as another, with less training, can find in light literature. Obviously, the mind must be refreshed and invigorated on the same principle

as the stomach; and we may consider the voice and cravings of the mind, no less than those of the stomach, the voice of nature. The kind of recreation must be suited, as Dr. Hill suggests, to the peculiar tastes of the individual and to the character of the fatigue or anxiety that has worn upon him.

Parlor-games, says Dr. Hill, serve as means of cure for those sufferings that arise from mental causes; they do so by diverting the mind without overtaxing it. Liebig once made a remark that had a great deal of truth in it: When any article is received into the stomach, a contest begins at once between the gastric powers and the intruder. If they conquer, the article was food; if they are conquered, it was poison; if it was a drawn battle, the article was medicine. What is intended for recreation may be pursued so far that it ceases to be recreation, and becomes, so to speak, a poison. The sanitary use of anything in the way of recreation, is the use of that thing to the extent of diverting the mind from injurious thoughts, but not to the extent of making the thing itself injurious by reason of becoming too absorbing to the mind. Dr. Hill quotes the late Prof. Pierce as saying that no game, and no toy, ever became permanently popular unless it involved some deep and peculiar mathematical or mechanical principle, and Dr. Hill offers the partial explanation that the presence of this deeper principle, underlying the game, prevents it from being digestible by any except those of strong power. It is questionable, however, if the most expert players of popular games think much of the mathematical or mechanical principles involved. But this makes no difference in the value of games as amusements; one that would stop to demonstrate the mathematics of a billiard-shot would never become an expert at the game.

Against some of the games that may be used with advantage for their sanitary value there is a great deal of prejudice. Naturally, what is valuable as a medicinal agent is not suitable for an article of diet. Hyper-moralists—we know of no other name for them—tell us that certain games are immoral because played by immoral people for wrong purposes; that backgammon is conducive to gambling, as well as cards. In the same way it may be said that horseback riding is conducive to gambling on horse-races; and history tells us that a certain King of England died of

eating too plentifully of lampreys, which were considered a good article of food. The fact is, one must always draw the line at proper use, not going to abuse. But who shall absolutely deny to the invalid the recreation to be obtained from what, if its proper use be not overstepped to abuse, will divert and recreate and relax the mind and body as nothing else will. The invalid may wish to read, or he may not; he may wish to engage in conversation or he may not; he may wish to sit and think or he may wish to be so occupied that he will have no time nor opportunity for introspection. He finds invigoration in a horseback ride on an empty stomach; or he may prefer, as did the Frenchman, that the horse's stomach be empty. To a Morphy or a Steinitz a game of chess with an ordinary good player would be mental diversion without mental work, but the game of chess is too severely intellectual to afford relaxation to the mind of an ordinary player. The therapeutic value of a game, as Dr. Hill points out, depends upon its adaptation to the individual tastes and need of the person who takes it up; and must be such as to interest him and keep his attention, but not such as to absorb, excite and fatigue him. His native and acquired tastes, his age and habits of life, the state of his health, the causes of his fatigue, or illness—all these and other similar causes, will influence the effect that any particular game or amusement will have upon him; and in the exercise of a sound common sense, by himself and his friends, he will select and vary his amusements as carefully as he selects his various occupations, or chooses his diet.

EDITORIAL NOTES.

SPONTANEOUS RUPTURE OF THE VAGINA DURING LABOR.—DÜRRSEN describes, in a recent number of the *Berliner Klinische Wochenschrift*, a case in which the vagina was ruptured during labor by pelvic contractions and an abnormal presentation. The patient, aged 34, had given birth to twins twice, without difficulty, though she had a flat rickety pelvis. Footling presentation was diagnosed before the membranes broke, but the head could be felt to be easily movable, and the feet had evidently prolapsed below them. The vagina would probably have escaped damage had the membranes been ruptured at this time,

and the feet drawn down. The membranes ruptured spontaneously, and about half an hour later the pains suddenly ceased, and severe abdominal pain was felt. In the lower part of the abdomen was felt a globular swelling—the body of the child—and to its right was the uterus, strongly contracted. The child had been forced partly into the abdominal cavity; it was easily delivered by the feet, after which the placenta and a good deal of blood came away. A large rent was found at the insertion of the vagina into the left side of the cervix, and the laceration extended into the broad ligament. The cavity above the laceration, and the vagina, were packed with iodoform gauze. Several times during convalescence the temperature rose, but without symptoms of peritonitis, and the patient got up within a month.

HYPODERMATIC INJECTIONS THROUGH THE CLOTHES.—A writer in the *Texas Courier-Record of Medicine* advises the following method for preventing unnecessary pain and abscesses:

Draw the clothing tightly over the site selected for the introduction of the needle, and when the syringe is charged and ready for use, take hold of the needle with the thumb and forefinger of the right hand at a distance from its point that will gauge the depth to which you wish to insert it—then with a sudden, firm motion plunge the needle perpendicularly into the tissues until arrested by the thumb and finger. Then change hands, steady the instrument with the left hand and push the piston slowly and steadily down with the right. When the instrument is used in this way it very seldom gives any pain and, if the contents be deposited deep down in muscular tissue, it seldom produces even soreness of the part and never an abscess. Withdraw the needle as suddenly and quickly as it was inserted.

Before using the syringe in this way one should certainly be very careful that the clothes through which the needle is passed be absolutely clean—and of this it is almost impossible to be sure. Possibly the clothing may rob the puncture of its painful qualities, and the solution of all likelihood of causing abscess; but it is certainly most improbable.

IMPACTION OF THE TIP OF A BILLIARD CUE IN THE EYE is reported by DR. WM. ELLERY BRIGGS, in the *Sacramento Medical Times*, for September, 1888. The patient was first seen three days after

the injury, when the lids were very œdematous, the wound partly united, and the cornea hazy and slightly ulcerated; vision was defective, the eye somewhat prominent, and there was a purulent discharge from the wound. Probing the wound gave vent to some pus, but a foreign body could not be positively detected. After two days' treatment the condition of the eye was worse. The wound was then enlarged and dilated with a pair of dressing forceps. A foreign body was felt, which was removed by means of sharp-toothed forceps. It was the leather tip of a billiard cue, greatly swollen, and measuring about two-thirds of an inch in diameter and one-third in thickness. The eye then began to improve under atropine, iodoform, sublimate solution, etc. A leucoma covers a large part of the cornea.

CENTRALIZATION OF MEDICO-SANITARY SERVICE was discussed at the recent meeting of Swiss practitioners at Lusanne, in May. It was unanimously resolved that "it is highly necessary at least to establish official relations between the medical corporation and the Federal Council. Drs. De Cérenville and Souderegger sketched the proposal as follows: 1. The creation of a permanent federal Sanitary Commission, of a permanent council, which is to be consulted by the federal authorities in regard to every important sanitary measure. 2. The appointment of a permanent federal secretary for sanitary affairs, who is to be a medical man selected by the Medical Corporation. His office would be a central bureau for all kinds of information relating to public hygiene, sanitary and professional questions, Swiss and foreign statistics; and would deal with food supplies, epidemics, secret remedies, etc.

HYDATIDS OF THE BRAIN.—DR. DAVIES THOMAS, of Adelaide, read an analysis of 97 cases of so-called hydatids of the brain before the Intercolonial Congress of 1887. The *tænia echinococcus* and *tænia solium* are found in the human brain in the cystic condition. When dogs are admitted freely to dwellings and to sources of drinking water the *echinococcus* will be more common. The *echinococcus* forms a much larger tumor in the brain than does the *cysticercus celluloseæ*. In other organs the *echinococcus* cyst has a fibrous capsule, but in the brain this seems to be wanting. The cyst is more commonly in one or the other of the hemispheres of the brain, and but rarely in

the cerebellum. The only symptoms that seem to be common to the larger number of cases are headache, blindness, and convulsions.

PHOTOGRAPHING A NUISANCE.—One of the members of the New York Health Department has secured the conviction of the owner of a smoking factory chimney by photographing the top of the chimney in various stages of smokiness. A detective has recently secured the conviction of a violator of the Sunday Liquor Law by making an instantaneous photograph of the inside of the saloon, with a group composed of the saloon-keeper and several more or less prominent citizens. This is a new field of usefulness for the camera, the testimony of which may be relied upon always. Possibly the portable camera may yet be a part of the outfit of the sanitary inspector.

GLASGOW POLICE AND AMBULANCE WORK.—The Glasgow Police Force is being instructed in ambulance and emergency work on an extensive scale. Dr. Kennedy Dalziel gives lectures and practical instruction to a certain number of men from all divisions four days in each week. Examinations will be held, and the successful men will receive certificates of proficiency, and will be entitled to wear the red St. Andrew's cross on the right arm to indicate that they are competent to treat injured persons.

A MINISTER OF PUBLIC HEALTH.—At the recent annual meeting of the British Medical Association Mr. BRINDLEY JAMES raised an important medical and political question as to the need for a Minister of Public Health. Sanitarians will probably agree that there should be a "Department of Public Health" in every government. Public health is no longer a local matter, but a national, affecting the whole people. Local sanitation would not be affected by a central authority, but could be more efficiently carried on.

LAKE COUNTY, ILLINOIS, MEDICAL SOCIETY.—On September 6 a number of practitioners of Lake County met at Waukegan and organized a County Medical Society. The following were elected officers: President, Dr. L. H. Tombaugh, Milburn; Vice-President, Dr. Wm. M. Sweetland, Highland Park; Secretary, Dr. A. C. Haven, Lake Forest; Treasurer, Dr. J. M. G. Carter, Waukegan.

TRANSACTIONS OF THE NINTH INTERNATIONAL MEDICAL CONGRESS.—We have reliable information that the last proof sheets of the fifth and last volume of the Transactions have been read and returned to the printer; which justifies the expectation that the whole work will be complete and ready for distribution before the end of the present month.

A CORRESPONDENT in Ohio sends the following interesting information: "The Northwestern Ohio Medical College at Toledo, Ohio, has reduced its fees to twenty-five dollars. The only thing now lacking is a good corps of didactic lecturers for its students who are not required to furnish evidence that they can either read or write."

THE SOUTHERN SURGICAL AND GYNÆCOLOGICAL ASSOCIATION did *not* meet, as heretofore published, on the 11th, 12th and 13th of September in Birmingham, Alabama; but the meeting has been postponed till the *first Tuesday* in *December* next, in consequence of the present quarantine against yellow fever.

MINISTER VON GOSSLER, it is said, has announced that he will secure the coöperation of the German Government in suppressing all advertisements of secret remedies in Germany.

DR. JOHANN DLAUHY, the veteran hygienist of the Vienna School, died on July 31, in his eighty-second year.

SOCIETY PROCEEDINGS.

Obstetrical Society of Philadelphia.

Stated Meeting Friday, June 8, 1888.

DR. DACOSTA IN THE CHAIR.

DR. C. B. PENROSE reported

TWO CASES OF EXTRA-UTERINE PREGNANCY;
LAPAROTOMY; RECOVERY.

M. C., æt. 32, had had four children, the last seven years ago, and two miscarriages, the last eleven years ago. She was treated for syphilis and uterine retroversion in 1883. She applied for treatment again on February 6, 1888. She had been bleeding profusely from the vagina for thirteen days, had suffered with continuous sharp pain in the left side for the same length of time. The pain and bleeding had started suddenly after

heavy lifting. There were no signs of pregnancy. Vaginal examination revealed a small retroverted uterus, and a tender, cystic mass about the size of a duck's egg lying to the left of the fundus. Three days later the mass was again examined and found to have increased to the size of a large orange. Laparotomy was performed Feb. 10, 1888.

The left tube was found distended at the outer half by a cyst the size of an orange. About three ounces of recent blood-clot was found in Douglas' pouch. The cyst was very friable and easily ruptured. During the removal a considerable quantity of old blood-clot escaped into the peritoneal cavity.

The left ovary was independent of the cyst in the left tube. The right ovary was cystic, and was also removed along with the right tube.

The convalescence of this woman was uneventful. She has menstruated naturally since the operation. Three months after the operation her breasts became enlarged and painful, and she was able to squeeze milk from them. This secretion of milk lasted for two weeks until stopped by belladonna ointment. These mammary symptoms were the only signs of pregnancy exhibited, before or after the operation, and I wish to ask the members of the Society whether it is not an unusual occurrence for this secretion of milk to take place so long after the removal of the product of conception?

Case 2.—E. B., æt. 28, has had four children, the last one a year ago. She had not menstruated since her last labor until two months before she presented herself for treatment. She then began to bleed profusely, and to suffer with great pain in the left side. For the last few weeks the bleeding had been accompanied by the discharge of shreds from the vagina. Vaginal examination revealed a large cystic mass to the right of the uterus.

Laparotomy was performed May 22, 1888. To the right and posterior to the uterus was a blood cyst about the size of an orange. The cyst was firmly adherent to the posterior surface of the uterus, and to the right ovary and tube, and the right tube opened into the cyst. As you will see from the specimen, this cannot be called a tubal pregnancy, as the first case, where a tube is distended by a cyst containing the product of conception. In the second case the tube opens into the cyst. In each case there was disease of the opposite tube and ovary, the ovary being in each instance as large as a good sized egg. The second patient is now out of bed.

DR. M. O'HARA: Dr. Penrose asks with reference to the presence of milk in the first case. I have seen one case in which milk never appeared. The mother was delivered at full term, and the child died. Dr. O'Hara does not think belladonna has any effect in arresting the secretion of milk.

DR. WM. GOODELL said that anything producing irritation of the genito-urinary organs may cause the appearance of milk in the breasts. The presence of fibroid tumor may even do so.

DR. JOSEPH HOFFMAN reported a case of

PERITYPHLITIC ABSCESS ORIGINATING IN APPENDICITIS.

exhibiting the specimens.

The patient, Mrs. B., married, with three children. When first seen she had a pulse of 128 and a correspondingly high temperature, and was unable to stir in bed without extreme pain. Careful questioning elicited the information only that eight days previous she had slipped from a chair, causing severe pain thereby in the right iliac region. This continued up to the time at which I was called in, when she was compelled to take her bed.

The duration of her trouble, according to her own statement, was limited to a little more than a week, though in this connection she mentioned the occurrence, previous to menstruation, of an ill-smelling vaginal discharge. Examination *per vaginam* discovered the presence of a tumor to the right alongside the uterus, the touch of which gave her much pain. The rectum was empty, she having had a dysenteric attack the previous day. External examination was so painful that I did not attempt it. The pain in her back and right leg was intense. I decided that operation was necessary and called in Dr. Joseph Price for consultation, but, examining under ether, was somewhat uncertain as to the condition.

Operation being decided upon, an opening was made in the median line and an exploration made. The cæcal portion of the intestine was found matted down, and was freed after much difficulty. The appendix was almost completely buried in pelvic tissue, and the temptation was great to tie it off piece by piece, though it was afterward enucleated by persistent effort. The cæcal portion of the bowel was almost gangrenous in spots and nearly ulcerated through.

Surrounding this portion was a quantity of stinking pus, about 2 ozs. The pelvis was carefully washed out, no antiseptic being used, and a drainage-tube introduced into the cul-de-sac, and a rubber tube led from the fossa, through the incision, which was closed by seven deep and superficial sutures. Nothing was done with the bowel save to cleanse it. The bowels were at first moved by enemata, and after a large quantity of scybala was discharged, calomel in $\frac{1}{6}$ gr. was given to clean the tongue and relieve bilious vomiting.

The patient made an uninterrupted recovery, all the stitches being removed, as well as the tubes, by about the tenth day. The patient now, at the twenty-fourth day, is sitting up, entirely free from pain.

A curious feature of the case is that after re-

moval of the offending appendix, the patient in three days remarked she had never been so free from pain for two years, then going on to give exact history of her trouble, all of which pointed to perityphlitis. Her pain had become so much a part of her that she did not seem to recognize it as foreign.

The points principally to which attention may be called are the closing of the incision, and the location of the same. Although central, drainage was perfect, and though sutured, it promptly healed, showing, I think, that dogma, both as to location and to allowing the incision to remain open, is not wise, as in this case the central incision enabled us to remove at the same time an ovarian hæmatoma, otherwise out of reach, and as drainage was perfectly obtained. These points for such operation are worthy of special consideration.

As to some points in the diagnosis, I shall not refer, leaving them to Dr. Price, who so kindly worked with me, I would only venture the opinion that here, as in all other pelvic surgical diseases, absolute diagnosis is very often impossible, depending, as it does, so much on an emesis which, as in this case, is little to be relied upon.

DR. CHAS. B. PENROSE: I would ask whether or not the pus was encysted around the cæcum, or free in the peritoneal cavity.

DR. HOFFMAN said the pus became evident only on raising the cæcum.

DR. PENROSE said the cases in which it is proper to make the incision over the cæcum are those in which there is an encysted abscess around the cæcum or the appendix. If there is free pus in the peritoneal cavity, a median incision would probably be better.

DR. GOODELL said that he on several occasions had been obliged to sever the appendix from its attachment, in operations for ovarian tumors, and the operation has seemed to have no effect. It seems to be a useless appendage. He did not know that modern research had thrown any light upon its use. In removing the appendix, he simply ligated it with silk and cut it off, carefully squeezing the end so that no fecal matter should remain.

DR. JOS. PRICE: A few years ago ovariologists regarded the appendix as sacred, as something that should never be touched. The case reported is one of great interest. The woman had complained for two years, her trouble evidently beginning in an appendicitis. The cæcum was so much thickened and so low down in the pelvis, as to suggest tubal disease. She however had good history and several healthy children, the youngest two years of age. The presence of the tortuous body on the right side determined the choice of the median incision. On opening the abdomen, the small hæmatoma was first removed. Afterwards the cæcum was dealt with. The course of the

case was all that could be desired. Dr. T. G. Morton teaches lateral incision and non-closure. As to the first, circumstances should influence the choice. As to the second, he did not believe in it at all. We are too far advanced in surgery for such procedure.

DR. J. V. KELLEY said that the general practitioner sees more cases of perityphlitis than the specialist, and he was disappointed in not hearing more about the history of the present case. He was also surprised that this case occurred in a woman, the disease being much more common in men. The existence of pain for a year or two would be against the existence of perityphlitic abscess. Over that time perityphlitic abscess is an acute disorder and runs an acute course.

DR. J. PRICE does not believe the view that perityphlitis is necessarily acute. He knew of a case of Dr. T. G. Morton, in which the operation for the trouble was repeated at the end of a year, and the appendix removed. Here the trouble was recurrent, gradually growing worse, and necessitating the second operation.

DR. M. O'HARA cited in substantiation of Dr. Price's views, the case of his own child, in which inside of eleven months there were two or three attacks. For four or five months he was in perfect health, although the condition (appendicitis) existed. Another attack followed, and death from septic peritonitis resulted.

DR. M. PRICE believed that the peritoneum can accommodate large quantities of pus for a time, just as abscess in other parts of the body can be tolerated.

DR. WILLIAM GOODELL thought that perityphlitis, like any other form of inflammation, may exist for years. He thought Dr. Kelley had narrowed the question down too far.

DR. HOFFMAN held it a mistake to believe inflammation cannot be present in these cases without the presence of a well-defined tumor. It is easy to make a diagnosis after operation, as is too often done. Pages could have been written after this operation on the diagnosis of perityphlitis, but *before* operation it was impossible, because there was no history. There was nothing but the inflammation of the appendix to cause the symptoms of which she complained.

DR. J. V. KELLEY thought no one would diagnose perityphlitic abscess without the presence of a tumor. The pericæcal tumors undergo resolution spontaneously, and abscesses do not form.

DR. J. B. DEEVER drew a distinction between appendicitis and perityphlitis, and believed very few cases of inflammation about the appendix undergo resolution.

DR. G. M. SHOEMAKER cited a case which he thought proved a termination by resolution in one such case.

DR. WILLIAM GOODELL presented a specimen of

OVIDUCTS AND OVARIES DISEASED BY GONORRHOEAL INFECTION.

The ovaries were enlarged by cystic and interstitial degeneration. The meso-salpinx was wholly absorbed, the fimbriated extremities of the oviducts were enlarged into a bunch of cysts, and the adhesions to the broad ligament were firm.

History as to the infection was a clear one. The husband had the gleet, and directly after marriage the wife's health began to fall from pain and reflex neuroses of a high grade. By vaginal examination, the concurrent implication of oviducts and ovaries was very manifest, as both organs were readily differentiated. The patient did well.

DR. GOODELL also exhibited a

SOLID OVARIAN TUMOR OF SUSPECTED MALIGNANCY.

The girl from whom he removed it was only 16 years old. It had grown very rapidly since it was first discovered a year and a half ago. It weighed 6 pounds, and for its removal needed an incision of nearly twelve inches. The pedicle was a very broad one. Some ascitic fluid was present. This patient was also doing well.

DR. GOODELL also exhibited a

FIBROID UTERUS WEIGHING 18 POUNDS.

A rapid accumulation of a large amount of ascitic fluid rendered the operation imperative. The patient had, on account of pressure upon the diaphragm, to be anesthetized in the sitting posture, and it was only after removal of the fluid that she could be safely placed in the recumbent posture. The incision needed for the removal of the tumor was a very long one. The pedicle was treated extra-peritoneally, by Kœber's wire clamp. Thus far all the symptoms are favorable, but as only forty-eight hours had elapsed since the operation, the patient was not yet out of danger.

DR. PRICE was glad to hear Dr. Goodell say operation is the only treatment for such cases. He never operates simply for relief of nervous symptoms, but wants actual disease.

DR. C. B. PENROSE exhibited specimens removed from a patient who had been treated several months, in 1884, for

CHRONIC CELLULITIS,

by the usual applications. She was married, and had two children, the last five years ago. In 1886 she returned for treatment. Diagnosis, cyst of left ovary and tube. She was again treated by the common applications. In 1888, one week ago, she returned for treatment, and pyosalpinx was diagnosed. The tubes and ovaries were found down in the hollow of the sacrum. The left ovary contained one drachm of purulent material.

DR. PARVIN regards the extract of hæmatoxylin the best astringent for chronic diarrhœa in children.

FOREIGN CORRESPONDENCE.

THE SALZKAMMERGUT AS A HEALTH RESORT.

St. Wolfgang—Ischl—Gmunden—St. Gilgen—Altersee—Unterach—Salzburg—Linz.

It is known to most medical men that the *Nach-Kur*, or After-Cure, is quite as important in the thorough treatment of such cases as find Carlsbad beneficial, as is the immediate drinking of the water. So as the time draws near which makes a change desirable for the patient, the question becomes an all-engrossing one, "Where shall I go to have quiet, good air, good food, congenial environment, and the services of a skilled physician?" These inquiries naturally associate themselves with considerations of cost of transit, and of ways and means generally. A patient whose system is experiencing the effects of the Carlsbad Cure has neither the physical strength nor the desire for long journeying. It is imperative also that the spot selected for convalescence should be as excellent as possible in all of the natural embellishments that round out an ideal summer home, and that it should not lack in the human devices that are necessary to the building up of physical strength.

For the purpose of aiding physicians in an intelligent differentiating, as well as to aid them in giving practical hints to such as are coming to Carlsbad, I propose to take up the discussion of some of the leading quarters that are desirable for invalids, embracing in this, a consideration of locality, of railway transit, cost, hotels, etc. This seems desirable, because during two seasons in which I have been in Carlsbad, out of the very many Americans whose acquaintance I had made, the question of the *nach-kur* seemed always to be a perplexing and a troublesome one. Beginning with the Salzkammergut, I shall cover the following resorts: Linz, Gmunden, Lambach, Ischl, Altersee, St. Wolfgang See, St. Gilgen and Salzburg.

From Carlsbad to Salzburg there is a direct train, leaving at about 8:30 o'clock in the morning, and making the trip in about fourteen hours without change of cars. Ischl is a drive—and a beautiful one—of between two and three hours from here. Altersee, St. Wolfgang, and St. Gilgen are short and lovely excursions, by carriage, from Ischl. The price of a ticket (second class) to Salzburg is 20 florins 62 kreuzers.

My family and I, who had determined on St. Wolfgang, and were desirous of making the journey as easily as possible, went first to Budweis. Leaving Carlsbad in the 8:30 morning train, arriving at 3:30 P.M. Tickets, second class, 11 fl. 82 kr. Here we stayed over night at the Silberne Glöcke Hotel. We took the accommodation train the next morning at 6:30 (this being the only

train that one can make use of unless he wait for the fast express, which does not leave till the afternoon), and arrived at Linz at 11:30 A.M. The tickets from Budweis to Linz cost only 2 fl. each. At noon of the same day we took the Vienna express from Linz and arrived at Ischl, after a rarely beautiful ride, of mountain, valley, and lake, at three in the afternoon, the tickets costing between 3 and 4 fl. We then took a carriage—which for three adults and two children cost 7 fl.—and drove in a little over two hours to St. Wolfgang. This made an easy and enjoyable ride. If one prefer, the journey can also be made *via* Munich, Rosenheim and Salzburg. From Carlsbad to Munich is a ride of twelve hours (Hotel Four Seasons), and from Munich to Salzburg *via* Rosenheim it is seven and one-half hours. One can go to Munich, then to Innsbruck and Salzburg. The road from Innsbruck is one of the most charming in Europe.

St. Wolfgang, on St. Wolfgang See.—This place is perhaps the loveliest in the Salzkammergut. It is a very old market town of 700 inhabitants. The lake is 549 m. above sea level, and is 12 km. long by 2 km. wide, and is 114 m. deep. It is hemmed in on all sides by mountains ranging from 1780 m. to 2000 m. in height. The water of the lake during the summer months has an average temperature of 17° R., and is pleasant for swimmers. The air is bracing without being cold, and the days are mild without being enervating. Take it for all in all, it is the most restful, healthful and altogether beautiful place that I have seen during a long sojourn abroad. There are two excellent hotels *Peterbräu* and *Weissen Ross*. The former is higher up, with a magnificent view; the other is directly at the water edge. At the *Peterbräu* rooms with a lake view, during the season, which begins in July, range in price from 2 fl. 25 kr.—that is, for a room with two beds. Rooms with balcony are more expensive. Rooms without the lake view are much cheaper. Board is 3½ fl. for each person, daily. It is perhaps cheaper to board *à la carte*, because one portion often is large enough for two, and at the end of each week ten per cent. is deducted from the entire amount of the week's bill. The situation of the *Peterbräu* is almost ideal. It would be difficult to conceive a more perfect picture of water, meadow and mountain. The walks are various, so that the Oertel treatment can be thoroughly observed. The food is simple, but well cooked and ample, while the milk is fresh and rich. For an After-Cure, nothing better could be chosen.

Ischl.—This fashionable and world-renowned summer resort is situated on the river Ischl where it empties into the Traun See. It is so surrounded by mountains that it seems to be quite shut off from the entire world. It is extremely rich in Alpine scenery, but lacking in the variety that

makes St. Wolfgang so attractive. It abounds in Hotels and Pensions, all of which are comparatively expensive. Hotel Elizabeth, Hotel Bauer, both elevated, near the Calvarier mountain; Hotel Post, Hotel Erzherzog Franz, Hotel Victoria and Hotel Austria, on the Esplanade; all of these first class. Bayrischer Hof, Stern and Krone, good houses, but of the second class. The Esplanade is rich with stores as attractive as those of Baden-Baden or of Carlsbad. There is a theatre, a Kurhaus, and a circulating library (mänhardt). Of baths there are Sool, Pine, Sulphur, Russian and Salt, also a swimming bath. There are 100 Milk and Grape-Cures. The kur tax for permanent guests is 8 fl.; for people of the middle classes, 6 fl., for women alone, 2 fl., children and servants, 1 fl. The music tax is 3 fl. The "Soolquellen" have been celebrated since 1828, and are very tonic and stimulating. Especially good for those who have taken a course of moor baths, and for those lacking in tone. On the Esplanade is a picture of Hygiea, bearing the inscription, "Man nennt als grösstes Glück auf Erden gesund zu sein—ich sage nein! ein gröss'res ist, gesund zu werden." The arrangement of the baths is perfect. Ischl has yearly between 6000 and 7000 guests, and upwards of 10,000 tourists. It is a place of much finery, tickling the fancies of those who revel in purple and fine linen. It is in every sense of the word fashionable, but I question much its entire fitness as a Carlsbad Nach-Kur. It is probably more widely known than any other place in the Salzkammergut.

Gmunden.—A lovely place. Grown of late to be as expensive and perhaps even more fashionable than Ischl, from which it is only a few moments removed, it also boasts of many hotels, of which I mention the Hotel Austria, on the lake; Hotel Bellevue, with an unbroken view and baths; Goldenes Schiff, on the steamboat landing; Hotel Laubhuber—all of these first-class. Second class: Goldenes Brunnen, Goldene Sonne, Hirsch. Kur-tax 4 fl. Music tax 2 fl. The esplanade runs for a mile along the border of the lake, affording magnificent views of the majestic mountains, impressive in their eternal silence, and of the Traun See. This lake is 12 km. long, 4 km. wide and from 28 to 191 km. deep, and is as romantically placed, in the lap of the gigantic peaks, green almost to their very tops, in shades that vary with the fickle rays of the sun, as any of the numerous bodies of water in this region. As at Baden-Baden, the patient can be quiet, entirely alone, with Nature only as a companion, or he can mingle with the throng in the ball-room, or satisfy his æsthetic though expensive desires among the shops that are made radiant to catch the guldens of the guests.

St. Gilgen is a quiet, restful, old-fashioned hamlet, on St. Wolfgang See, easily reached by boat from St. Wolfgang. It is cheap, unfashionable,

and charmingly situated. For those who demand *absolute* quiet, without any distraction whatever, it occurs to me that St. Gilgen would offer many inducements.

Altersee.—The Alter or Kammer See is the largest of the Austrian lakes, being 20 km. long and 2 to 3 km. wide. The little steamers run from Kammer to Unterach twice daily.

Unterach is a much sought after summer refuge, and is beautifully situated on one end of the lake. The hotels are the Post, Mittendörfer and Hofwirth, at any of which very reasonable arrangements can be made for a prolonged stay. The terms at the Hotel Altersee in Altersee are 2 florins a day for board, and for a *good* room with two beds between 2 and 3 florins. The country round about is somewhat less wild and more flat than at Wolfgang, but the walks are charming, and many people select Altersee in preference for a continued stay. Those who have been there for many summers continuously are loud in its praise.

Salzburg.—"Die Gegenden von Salzburg, Neapel, und Konstantinopel halteich," says Humboldt, "für die schönsten der Erde." Poets have sung its praises, travellers have written its beauties in letters of gold, and history has clothed it with an interest peculiarly its own. The natural splendor of its environs is that of Zermatt, but tempered with the refinement of a larger civilization and with its concomitant comforts. The air seems to be as invigorating as that of Saas in Grund, but not as rough and sharp. It is a *Kur-ort*—a Health Cure—of the very first rank. In natural beauty it has no rival. Its baths of all kinds, including the Moor, are of the highest order, and it combines everything that is necessary for mental rest, physical repair, æsthetic gratification and artistic ambition. It would be prolix to attempt a minute description, because Salzburg is known to most every one; it would be foolish to attempt word-painting, because even a Theophile Gautier would find himself handicapped in the attempt. It simply more than bears out all that has been written and said about it. The Hotel de l'Europe and Neblock are both as good as anything we have at home. Two people can have a comfortable room and board at either for from \$80 to \$90 a month, and I have no doubt that for a long stay much cheaper terms could be made. But there are rooms to be had everywhere for from 8 to 15 florins per week, and at the Mirabellgarten Kurhaus, or Zipfer Bierhalle, meals at all prices are always ready. Breakfast and supper (bread, eggs, tea, coffee, chocolate, etc.), can be had at Tomaselli, Koller, Oberkogler, Felber, or at many other coffee-houses. In this way two people could live for 5 or 6 florins a day. For patients making a *Nach-Kur*, or continuing here these baths, this *al fresco* life has great advantages—for fresh air and plenty of it is always prescribed. Libraries, museums and shops are in

abundance. The place is rich in reminiscences of Mozart, and the restlessness, the vagaries and the superstitions of the Middle Ages have left their finger-marks everywhere. I have never yet heard of a person who left Salzburg disappointed, or feeling that the actual had not more than equalled the prefigured.

Linz.—This town is best known as a bathing station for travellers from the north and east toward Ischl. It has direct connection with Vienna by boat (eight to nine hours) or by railway—by the latter also with Munich, Budweis, St. Valentin and Ischl. Its hotels are Erzherzog Carl, Goldenes Adler, Kanone and Goldene Löwe. It is prettily situated, but has no especial merit as a *Kur-ort*. This may also be said of Lambach.

Finally, I commend the Salz Kammergut to physicians who are sending their patients to European summer resorts, as being a complete realization of all that is most desirable. To add a suggestion would seem to spoil the general harmony. Nature has done its perfect work in an incomparable way, and man has added to it the comforts which modern civilization demands.

HORATIO R. BIGELOW, M.D.

LETTER FROM LONDON.

(FROM OUR OWN CORRESPONDENT.)

Lipianin—*Improvement of Watering-Places*—*Florence Nightingale*—*Epidemic Jaundice*—*The Lebel Rifle*—*Sir William Bowman*—*The Morgue in Paris*—*The Children's Jubilee Offering to go to the Hospital for Sick Children*—*Glass-blowers' Cramp*.

The new product known as lipianin is said to be a good substitute for cod-liver oil. It is proposed to make lipianin cheaply by the direct addition of pure oleic or erucic acid to olive oil. It is thought that cholesterolin which is contained in cod-liver oil, is of importance, and that if vegetable oils be used in place of cod-liver oil they should be made to contain cholesterolin. Others look upon cholesterolin as a most undesirable substance to be present in cod-liver oil, or in any other substance used as a food or medicament, since it is the principal cause of gall-stones. Professor Mering, who introduces lipianin to medical notice, says there can be no doubt that in the first half of the present century cod-liver oil was regarded as more efficacious than it is now supposed to be, and he attributes this to the fact that the article first used was the dark oil, which contained much more free acid; the steam-drawn oil now used being prepared as nearly as possible neutral. With regard to cholesterolin, the same Professor thinks that it is a great mistake to credit this substance with any properties as a food. He remarks that the yolk of a hen's egg contains about as

much cholesterin as can be obtained from three ounces of the best cod-liver oil, namely about four English grains, and maintains his opinion that lipanin is an excellent substitute for cod-liver oil.

Last year the Speaker of the House of Commons made a few graphic remarks on the mineral waters of Great Britain and Ireland, which were duly reported at a meeting of physicians at Leamington. On that occasion it was pointed out that if it was desired to promote the prosperity of our English spas, there must be certain developments which many of them did not at the present possess. The invalid did not merely want water and baths. There must also be the means of recreation, for the invalid who when well amused was half cured. English medical men were reproached for neglecting the spas of their own country, but it must be remembered that they had to take a great variety of subjects into consideration. The bromo-iodine spa at Woodhall, in Lincolnshire, has only at present a local reputation, though Mr. Burney Yeo claims for it that as a health resort it will no doubt have a European or even a world-wide fame, and such is the case of others. And should any of them be recommended to a lady by her physician, he will as likely as not be at once asked whether Homburg or Weisbaden would not do as well. A young man in the Guards objected to Harrogate because he was afraid of meeting his tradesmen there, and in a like manner a married man refused to go to Bath because his mother-in-law had already been recommended to go there. Numerous mineral springs in England are known to chemists and are shown by analysis to be similar to those of Vichy and other Continental resorts, but hitherto it has not been deemed advisable to risk any capital in the view of making them fashionable health resorts, simply because the attraction of Continental travel and thorough change of scene and of climate are too great, and draw annually from Great Britain enormous sums of money.

Miss Florence Nightingale, the heroine of the Crimean war, is now a confirmed invalid. The long hours of standing during her hospital work affected her spine, and she has been for some years past an in-patient at St. Thomas' Hospital. She is now in her sixty-ninth year.

From Glasgow the medical officer of health reports a group of cases of what has been described as "epidemic jaundice." They were eleven in number and occurred in five families. Nearly all the patients were children, and there were two deaths. A woman, aged 36, was the first to have it. She died after two months illness. Her child, aged 14 months, was taken ill the day before its mother's death and is still jaundiced. In one family six of the children have been ill. All the cases have occurred in the same small district. The investigation of the present affected area is not yet complete, but the drainage is for the most part "sur-

face drainage," and the house drains and connections are very defective. The precise causation of outbreaks is not clear but in numerous cases it is thought by Dr. Russell to be distinctly associated with sanitary defects and nuisances, such as stagnant sewage, choked drains, and the like.

The new French instrument of destruction, the "Lebel rifle," is a wonderful weapon. Members of the Academy of Medicine wishing to diagnose the physical consequences of wounds inflicted by the bullets of the gun recently had experiments made on twenty corpses. The bodies were placed at the ordinary firing distances, from 200 yards up to a mile or so. The bullets whizzed through the bones and pierced them without fracturing them, as is done by the bullets of the "Gras rifle." The wounds, if they may be called so, which were inflicted were small in their punctures, and consequently very dangerous and difficult to heal. Injuries inflicted at short distances were so considerable that in the opinions of the surgeons they would be almost incurable.

A provisional committee has been formed to present Sir William Bowman with some public acknowledgement for his great services to ophthalmology and to physiological science. The testimonial is to take the form of a portrait of himself painted by an eminent artist. No limit is placed on the amount of individual subscriptions, but it is hoped that the sum collected will be sufficient to enable a good reproduction of the portrait to be distributed to subscribers of at least two guineas.

The books of the Paris morgue show a steady yearly increase of the number of dead bodies received. Four hundred corpses were brought in 1830. In 1870 the number had risen from 400 to 800. The numbers rose from 807, in 1880, to 920, in 1881, and from 879, in 1882, to the unprecedented figure of 944, in 1883—the result of wilful murder, accidental death, or suicide.

The Children's Jubilee Offering to the Queen, which has exceeded £6,000, has been presented with a diamond brooch to Her Majesty, on behalf of the children, by Princess Victoria, of Teck. The money will be appropriated towards the completion of the wing to the Hospital for Sick Children, Great Ormond street.

Attention has just been drawn to the fact that glass-blower's cramp is a professional deformity of the hand. It consists in pronounced flexion of the fingers, occurring chiefly at the second joint. In France it is called *main en crochet*, or *main fermée*. It attacks the majority of workmen and is most pronounced in the oldest. No remedy is proposed by Dr. Poncet, who has been giving great attention latterly to the subject.

LETTER FROM PARIS.

(FROM OUR OWN CORRESPONDENT.)

Treatment of Diphtheria—Cocaine Solution Sprays in Bronchial Affections—Hot Water in Obstetrics—Electrolysis in the Treatment of Erectile Tumors—Advantages of Borax and Boric Acid—Pathology of Diabetes.

At a recent meeting of the Société Médicale des Hôpitaux, Dr. Gaucher made an important communication on the treatment of diphtheria. He stated that the false membranes being the source of infection, should be removed, their site being painted with a concentrated solution of carbolic acid and camphor, in alcohol, to which is added some olive or almond oil. The following is the formula of the solution he employs: Crystallized carbolic acid 10 grams, camphor 20 to 30 grams, alcohol 10 grams, the whole to be dissolved, and to this is added an equal quantity of oil. The strength may be varied according to the severity of the malady. The essential point of the treatment consists in the topical application of a caustic solution which is at the same time antiseptic, after the removal of the membranes. The latter is effected by vigorous rubbing with some cotton wool wound round a slender piece of wood, which has to be repeated morning and evening. Some of the members present observed that it was too difficult and painful an operation for the author to entertain any hope of its being adopted in practice.

Dr. Perron, of Bordeaux, made a communication to the same Society on the advantages of sprays of solutions of cocaine in various bronchial affections. Under the influence of a 2 per cent. solution of cocaine which is used in the form of a spray, the most violent fits of coughing are arrested in a few minutes. Phthisical subjects who are troubled with coughing and consequent insomnia at night, experience immediate and durable relief from this treatment. By this means opiates which are always more or less injurious after a time, are avoided. In acute bronchitis the action of cocaine is as advantageous. A notable modification takes place in the state of the pulmonary mucous membrane, and owing to the insensibility thus produced, the inflammation and the secretion are diminished. About ten or twelve inhalations, practiced by means of the spray producer placed near the mouth wide open, suffice to bring about prompt and satisfactory results.

In his thesis for the doctorate, Dr. H. Lorain, of Nancy, treated of hot water in obstetrics. The author explained that hot water at a temperature of 45° to 50° C. is an energetic stimulant of the smooth muscular fibre. It also has an action on the blood-vessels, manifested by an immediate and persistent contraction of the vessel, or by a momentary dilatation followed by contraction.

These two physiological facts explain the therapeutic effects so evident which these hot injections of 45° to 50° C. exercise on the uterine contraction. It is by their stimulating action on the uterine fibre that these injections constitute an oxytocic means so efficacious and so useful during labor. It is the double action exercised by the hot water on the fibre and the vessels which explains its efficacy as an agent of hæmostasis. Hot injections should be preferred as hæmostatic to cold injections, as cold water has an action less energetic on smooth fibre and, moreover, the vascular contraction due to cold might be followed by a reaction with paralytic dilatation, whence it may happen that the hæmorrhage, arrested momentarily, reappears with more intensity.

Dr. Redard lately read a paper at the Société de Chirurgie on the treatment of erectile tumors by means of electrolysis. The author accords to this treatment a superiority over the other means generally employed. He entered very fully into the mode of operation, and employs electrolysis only once in six or eight days. After the first application the tumor hardens; after the second, the morbid production presents important modifications. The apparatus he employs consists of a battery of continued currents, a galvanometer of intensity well graduated, needles in gold or in platinum, of half a millimetre in diameter and from eight to ten centimetres long. The operation may be performed by three ways of introducing the needles into the tumor: 1. By penetrating the morbid product with the positive and negative needle, at a short distance one from the other. 2. To introduce the positive needle alone into the tumor, the other pole of the battery fixed in the form of a plate on any part of the body. 3. To introduce the negative needle alone into the tumor. The current employed should be from 15 to 18 milliampères. In order to avoid all hæmorrhage, before withdrawing the needle or needles, the current should be reversed for a few seconds and brought to zero. The needle or needles should be removed only when no resistance is experienced. The author concludes his paper by the following propositions: 1. Electrolysis is the method of choice in the treatment of erectile and cirroid tumors. It succeeds wherever the other methods fail. 2. It affords protection against all accident of sloughing and of suppuration. 3. It acts with certainty and precision. The puncture with the positive needle alone should be recommended in the majority of cases.

In a paper to the Medical Society of Anvers Dr. Bedoin writes on the advantages of borax and boric acid. He states: 1. The borate of soda or borax, and particularly boric acid, possess incontestable antiseptic properties, the activity of which is not so small as is generally affirmed. Both are recommended for the preservation of alimentary substances, such as milk, butter, cheese.

eggs, butcher's meat. But owing to its almost absolute insipidity, boric acid should, for this purpose, be preferred to borax, the savor of which is disagreeable; both are absolutely innocuous. 2. Interiorly, the therapeutic employment of boric acid as an antiseptic has already given very encouraging results, which are of a nature to authorize its administration in the affections where, till now, carbolic acid was almost exclusively employed, for example, typhoid fever. 3. Exteriorly, the serious antiseptic properties of borax and particularly of boric acid, justify the generalization of their employment in surgery, notably in the practice of dressings after the method of Lister, also in certain affections of the urinary organs, of the eyes, ears, and of the skin.

At the Société de Biologie, Dr. Quinquaud read a note for Drs. Artand and Butte on the pathogeny of diabetes, in which the authors notice the organic alterations consecutive to neuritis of the vagus nerve. These alterations involve the greater part of the viscera: intestines, pancreas, stomach, liver, kidneys, etc. They are of the same nature which are observed in diabetes, and are accompanied by functional troubles which characterize this malady.

A. B.

DOMESTIC CORRESPONDENCE.

Physicians and Insurance Companies.

Dear Sir:—In view of the self-evident fact that all true life indemnity rests upon the accuracy and reliability of medical opinion and services, it would seem equally apparent that the profession is entitled to square dealing, at least from the great companies. Many of the latter in order to advance their interests have, of late, adopted a line of policy which violates the tenets of honorable dealing, and is unjust towards those whose assistance has proven in the past so valuable.

Solicitors for these companies are authorized to ignore the claims of established medical examiners, and boldly offer their patronage to any medical man who will bid for it by taking out a policy. It is natural, that those having acted as examiners—regularly appointed—should often be carrying all, and frequently more insurance upon their lives, than they feel able. Should this be true, it avails nothing that his services have stood between the company and heavy losses or the many good words dropped for the former during his relation as examiner, provided some other man can be induced to insure. To drop a man and transfer the patronage of the company to another for such a reason is worse than unjust—it is ungrateful.

Truly yours, X.

BOOK REVIEWS.

Early English Text Society. *THE ANATOMIE OF THE BODIE OF MAN.* By THOMAS VICARY, Searjeant of the Surgeons to Henry VIII, Queen Mary, and Queen Elizabeth; Master of the Barber-Surgeons' Company; and Chief Surgeon to St. Bartholomew's Hospital, London, 1548–62. The Edition of 1548, as reissued by the Surgeons of St. Bartholomew's in 1577. With a life of Vicary, Notes on Surgeons in England, Bartholomew's Hospital, and London, in Tudor Times, an appendix of documents, and Illustrations. Edited by Fredk. J. Furnivall, M.A., Hon. Dr. Phil., and Percy Furnivall, a student of St. Bartholomew's. Part I. London: N. Trubner & Co. 1888. 15 shillings.

This volume contains a portrait of Dr. Vicary, after Holbein, early plans of St. Bartholomew's Hospital (about 1560), Norden's map of London, 1593, map of Vicary's road from London to Maidstone and Boxley, and other illustrations. The "profitable Treatise of the Anatomie of Man's body, compyled by that excellent Chirurgion, M. Thomas Vicary, Esquire," occupies 86 pages. The appendix may possibly be considered the most interesting part, and covers 250 pages. It contains the grants to Vicary by Kings and Queens; extracts from City records as to Barts, Vicary, the Plague, London vagabonds, etc.; Vicary's will; Henry VIII's statutes relating to Surgeons; Supplement to the statutes; the Surgeons' compromise with the City as to serving on Quests; ten recipes by Henry VIII and his physicians. Poem, "What veins to bleed in," etc.; the 185 Freemen of the Barber-Surgeons' Company in 1537; the numbers of the other City Companies; ordinances of the Barber-Surgeons of London, 1529; ordinances of the Barber-Surgeons of York, 1592, and other matters.

As a contribution to the history of medicine this volume is of rare interest.

Early English Text Society. *A DIALOGUE AGAINST THE FEVER PESTILENCE.* By WILLIAM BULLEIN. From the Edition of 1578, collated with the earlier Editions of 1564 and 1573. Edited by MARK W. BULLEN and A. H. BULLEN. Part I.—The Text. London: N. Trubner & Co. 1888. 10 shillings.

This work was written just after the great Plague of 1563, and is edited by two namesakes of Dr. Bullein. This dialogue seemed to have dropped out of notice after 1596; in this year Nashe mentions it in his "Address to all Christian Readers," in which he writes: "Memorandum, I frame my whole Booke in the nature of a Dialogue, much like Bullein and his Doctor To-crub." This "To-crub" was anagrammatic for

Dr. Burcot, an expert in metals and minerals, and whose name appears in the State papers of the time. The editors are preparing some notes on the *Dialogue*, which, with a biographical and critical memoir of Dr. William Bullein, and copious extracts from his remaining works, will form a separate part. Lovers of the old and curious in medicine will find much in this *Dialogue* to interest them.

SECOND ANNUAL REPORT OF THE STATE BOARD OF HEALTH OF OHIO, for the Year ending October 31, 1887. Pages 374. Columbus: 1888.

Among other reports this volume contains reports of health of towns, on water-supply and disposal of sewage, and on various diseases, and on the adulteration of food, drugs, and drinks. It contains also a number of papers on sanitary subjects, as "Effect of Occupation on the Health of Individuals," by Dr. John D. Jones, "Especially Sources of Danger to Life and Health," by Dr. Thomas C. Hoover, and "The Hygiene and Care of Children by their Teacher," by Katherine Kurt, M.D.

MISCELLANEOUS.

EXTRAORDINARY VITALITY IN A CHILD.—Dr. W. A. Thompson, of Amplehill, England, gives in the *British Medical Journal*, an account of most wonderful vitality in a young child:

On Tuesday, July 17, two children aged respectively 4½ and 5 years, left their homes shortly after their dinner at 1 o'clock. They were seen during the afternoon playing together by the side of a pond, with shoes and socks off their feet, by a passing laborer, who shouted to them to leave the water, and it appears that the boys ran away frightened in different directions. The eldest boy arrived home some hours later on, and stated that he had lost his companion and knew nothing as to what had become of him. Search was made about the roads and paths where the children had been seen, but to no purpose. It was now getting dark, and the police being informed, a large party started off in search, some with lanterns and some with St. Bernard and retriever dogs. Rain fell nearly all that night, but the search was continued, night and day, for several days. It rained heavily frequently during this period.

All hope of finding the child was now abandoned. However, on the Sunday morning following (July 22) some young men and boys were having another look round the fields, when, at about 10 A.M., one of them thought he heard some groaning in a field of wheat near him, and, on going there, found the little boy sitting on the ground, not very far from the pathway. He was sitting upon his coat, with his little trousers drawn down over his feet, and crying out: "Mother, Mother! I am so hungry!"

How long he had been in that spot and in that condition of attire we cannot make out, and he is too young to give much explanation. When found he appeared to be in a semi-conscious state, and did not seem to know those around him; but after some hours he recognized his mother and brothers. With suitable treatment the child has completely recovered, without any subsequent illness which might be induced by starvation or exposure to wet and cold for the long period of five days and

nights, counting from the dinner-hour on Tuesday until 10 A.M. on the Sunday following.

During this time, as far as any one knows, the child had nothing to eat except the heads of growing wheat (which was in very poor condition at that time). He told me that he had eaten some, and we may presume he sucked water off the wheat and grass about him. Curiously enough the child had out with him a small tin box without any lid, and he states he tried to catch rain-water in it, but could not get any; the wheat being very high probably prevented him doing so, and also most likely kept him fairly dry. In appearance the child did not seem much the worse for his prolonged fast, and seemed as plump as any ordinary child; but the mother states that he was an unusually strong and fat boy.

Taking all things into consideration—the child's age, no proper food or drink for over 17 hours, the exposure to the cold and wet weather prevailing at the time, the misery and the loneliness it must have endured for so long a period—it seems somewhat remarkable that life was preserved.

GREAT GAIN.—Dr. John C. McVail says: "If the question be asked, Where is the proof that our preventive measures—our sanitation, vaccination, and isolation—have had the results we speak of, the answer is at hand. It is given by the Registrar-General in the language of figures. He points out that, according to the newest English life-table, the children born in England in any one year have now divided among them 'nearly two million years of life'—more than would have been the case thirty-five years ago. In England and Wales the annual mortality per million of population per annum has been as follows:

1861-65	1866-70	1871-75	1876-80	1881-85
22,595	22,436	21,975	20,817	19,310

Comparing the first period and the last, the difference is 3285 per million, and taking the population at 30,000,000, the total annual saving is about 100,000 lives. And if for every death there are twenty cases of sickness, then we have two million less cases of sickness in the first period. . . . You can count the cost of each case of sickness, of lost work, of doctors' bills, and so on, and also the monetary value of each of the 100,000 lives saved. And you can put all this as an income against the interest on the money spent in sanitary improvements, in water works, sewage works, vaccination grants, officials' salaries, etc., and even on this lowest ground—on this merely commercial basis—we find that cleanliness is next to godliness, resembles godliness itself in being 'great gain.'—*Sanitary Journal*, July 4, 1888.

DEMAND AND SUPPLY IN SNAKES.—Last year in Madras 1,492 persons were killed by snakes, while 255 snakes were killed, and no rewards were paid. In Bombay 1,206 persons died from snake-bite, while 266,921 snakes were destroyed, and Rs. 6,517 were paid as rewards for their destruction. The mystery is not explained by a further examination of the facts. In Bombay in 1885, 1,115 persons died from snake-bite, while the number in 1886 was 1,206, showing an increase of sixty-one victims, although 283,579 snakes had been killed in 1885. In Madras 1,487 persons died of snake-bite in 1885, and in 1886 the number was 1,492, showing an increase of only five deaths, while in 1885, 328 snakes were killed, and no rewards were paid. Again, in Bengal the number of deaths from snake-bite in 1885 was 10,112, whereas in 1886 it had been risen to 10,388, although 53,995 snakes had been killed in 1885, and only 31,204 in 1886. In the Punjab, where snake-killing has been energetically taken up, the victims numbered 686 in 1885 and 928 in 1886. Yet 47,576 snakes were killed in 1885, at a cost of Rs. 4,732, and 87,715 were destroyed in 1886, at a cost of Rs. 10,506.—*The Indian Medical Gazette*, May, 1888.

HEALTH IN MICHIGAN FOR AUGUST, 1888.—For the month of August, 1888, compared with the preceding

month, the reports indicate that dysentery, diarrhoea, cholera infantum, cholera morbus, remittent fever, typho-malarial fever and erysipelas, increased, and that measles decreased in prevalence. Compared with the preceding month the temperature in the month of August, 1888, was lower, the absolute humidity and the day and night ozone were less, and the relative humidity was the same.

Compared with the average for the month of August in the nine years, 1879-1887, intermittent fever, cholera morbus, whooping-cough, remittent fever, diphtheria, tonsillitis, cholera infantum, typho-malarial fever, influenza and diarrhoea, was less prevalent in August, 1888. There was no disease reported more usually prevalent in August, 1888.

For the month of August, 1888, compared with the average of corresponding months in the nine years 1879-1887, the temperature was lower, the absolute humidity was slightly less, the relative humidity was the same, and the day and night ozone were much less.

Including reports by regular observers and others, diphtheria was reported present in Michigan in the month of August, 1888, at 27 places, scarlet fever at 25 places, typhoid fever at 23 places, measles at 7 places.

Reports from all sources show diphtheria reported at 6 places more, scarlet fever at 8 places more, typhoid fever at 13 places more, and measles at 15 places less, in the month of August, 1888, than in the preceding month.

PHARMACEUTICAL MAPS.—We have decided to print Europe in several sectional maps, and without regard to any special order save that of having the material at hand to best serve our purpose. The coming sectional maps of Europe will be on a much larger scale than those heretofore given, and will therefore have even greater value in pharmaceutical, botanical and commercial interest than anything yet produced. We have been favored with the aid of some of the most eminent of scientists in Europe in the arrangement of the habitat of the plants, and congratulate our readers and friends on this pleasant feature of pharmaceutical fraternity which we shall duly acknowledge by giving suitable notice of their kindness when publishing the portions to which each have so generously contributed of their personal knowledge toward insuring a reliable pharmaceutical map of Europe.

Recently we have had a set of the three maps heretofore given (South America, Africa and Asia) reproduced on a scale suitable for college instruction. The first two maps are 7½ feet square, the map of Asia 7½ feet by 11 feet. Such maps cannot fail to be of great value to students at colleges of pharmacy and medicine, being specially adapted for lectures on *Materia Medica*.—*Pharmaceutical Record*, Sept. 1, 1888.

DISEASES OF WINE-TASTERS.—A German medical paper says: The diseases of wine-tasters were studied by Donnet, of Bordeaux, and Dr. C. Marandon, of Dijon. Wine-tasters are frequently suffering with disturbances similar to alcoholism, although the claret-tasters do not swallow the wine, but on the contrary, reject it, and even rinse their mouths afterward. In one case of Dr. Donnet's a man 32 years old used to taste every day thirty or forty samples of wine, occasionally liquors and rum, without ever swallowing any part of them. After two years he became very excitable, lost his appetite, did not sleep well, and suffered with disturbances of sensibility, pains in the breast, a feeling of weakness, difficulty in breathing. He improved after abandoning his profession, although a nervous debility still remained, as noticeable by the facility with which he was set in tears. Another statement made by Dr. Donnet is the great number of apoplexies in Bordeaux, where many persons drink one and a half litres of wine with each meal. This number exceeds the number of apoplexies in any city of the world. Dr. Marandon did not notice any symptoms of intoxication in Burgundy tasters, although some of them

would swallow the samples. He remarks that tea-tasters always swallow some tea, and this fact, he says, explains the nervous symptoms they are affected with.—*Mining and Scientific Press*.—*Sanitarian*, August, 1888.

RESIDENTIAL BUILDINGS FOR MEDICAL STUDENTS.—The medical staff of Guy's Hospital, with the consent and full assistance of the governors, have decided to build a residential college for the students. This will be erected on premises within the hospital precincts, on ground on which the first Nonconformist place of worship in London was situated. It is intended for the reception of sixty men, amongst which number will be included the resident staff of the hospital, the house surgeons, house physicians and others, who will be in telephonic communication with the hospital buildings. Every convenience will be provided and amongst other things a gymnasium will be included, for the use of the residents; this is as it should be. The building is calculated to cost £20,000, the whole of which has been already subscribed.—*Lancet*, July 28, 1888.

RE-IMPLANTATION OF BONE.—After his Address on the Surgery of the Brain at the recent meeting of the British Medical Association, Dr. Macewen gave a demonstration of cases so remarkable that it alone would suffice to render the Glasgow meeting memorable in the annals of surgery. Many of the patients whose cases have been described in the address were present, but the many eminent surgeons who attended were greatly interested also in the examples of reimplantation of bone; the head cases afforded many instances, but the most remarkable was a boy, in whom the whole shaft of the humerus had been reformed from grafts, forming a useful link. The audience was large, and Dr. Macewen was loudly applauded and received numerous congratulations on his brilliant results.—*British Medical Journal*, Aug. 11, 1888.

BICARBONATE OF SODIUM AS A MILK PRESERVATIVE?—The conseil d'hygiène of the Department of the Seine have taken a decided stand against the use of bicarbonate of sodium for the preservation of milk. The chief arguments in favor of the position taken are: the short time that it now requires for the milk to reach Paris and be distributed; the easy application of cold, which preserves it fully as well without changing its composition; the unpleasantness of the sodium bicarbonate, which, when decomposed by lactic acid, yields a purgative salt very injurious to the health of children.—*Zeitschr. f. Nahrungsm. u. Hygiene*, March, 1888.—*Sanitarian*, August, 1888.

Buenos Ayres is to have a water supply, the cost of the works for which will be fifty million dollars.

Official List of Changes in the Stations and Duties of Officers Serving in the Medical Department U. S. Army, from September 1, 1888, to September 7, 1888.

A Board of medical officers to consist of Major Charles H. Allen, Surgeon; Major George M. Sternberg, Surgeon; Major Henry McElderry, Surgeon; Capt. Edw. C. Carter, Asst. Surgeon, is constituted to meet in New York City on October 1, 1888, or as soon thereafter as practicable, for the examination of Asst. Surgeons for promotion and of candidates for admission to the Medical Corps of the Army. S. O. 203, A. G. O., September 1, 1888.

Capt. J. C. Worthington, Asst. Surgeon, ordered from Ft. Crawford, Col., to Ft. Townsend, W. T.

Capt. J. D. Hall, Asst. Surgeon, ordered from Ft. Townsend, W. T., to Ft. Niagara, N. Y.

Capt. P. R. Brown, Asst. Surgeon, ordered from Ft. Niagara, N. Y., to Ft. Sidney, Neb. S. O. 206, A. G. O., September 5, 1888.

ADDRESS IN STATE MEDICINE.

RECENT ADVANCES IN STATE MEDICINE.

The Annual Address by the Chairman of the Section on State Medicine, Delivered at the Thirty-ninth Annual Meeting of the American Medical Association, May, 1888.

BY HENRY B. BAKER, M.D.,

SECRETARY, STATE BOARD OF HEALTH, LANSING, MICHIGAN.

The By-laws of this Association require that "The Chairman of each Section shall prepare an address on the recent advancement in the Branches belonging to his Section." Thus the subject of this address is fixed; yet, most of us are too busily occupied with professional or official duties to study carefully all of such work reported in all parts of the world, especially as the field in State Medicine is so very extensive, depending upon, and utilizing, as it does, the progress in most of the medical and allied sciences. One must have a very broad view, much leisure, a good knowledge of several languages, and be familiar with the requirements of practical sanitary work, in order to summarize fully the "recent advancement in the Branches belonging to" this Section. I cannot hope to accomplish so much, and, if I could, you could not listen to it in forty minutes,¹ but I shall do the best I can in the time at my disposal to place before the Section a summary of those recent advances in State Medicine which have attracted my attention and have impressed me as useful for our encouragement, for the suggestion of errors or obstructions to be avoided, or of new methods or combinations of facts useful for our progress.

GENERAL PRINCIPLES UNDERLYING USEFULNESS OF STATE MEDICINE.

Sanitarians are not so much nuisance abaters as formerly were the hygienists; and they are more disease-preventers. In the public-health service generally, methods are coming to be more instructive, and less dogmatic and mandatory. Such opposition as that of Herbert Spencer, to boards of health constituted according to the old ideal, does not at all apply to State Boards of Health constituted on the modern plan which

makes their chief functions the collection, collation and dissemination of facts which teach the causation of disease, the best means for avoiding and preventing sickness and deaths, and which facts are from sources so extensive as to be entirely beyond the reach of individuals, but which the people as a whole, through their governmental representatives, can easily collect, collate, and place before all classes of people, to be utilized by such as are sufficiently intelligent.

Modern methods of sanitation are thus in harmony with the law of "the survival of the fittest," if we consider, as I do, that the most intelligent classes, who obey the teachings of sanitary science are best fitted to survive.

Any narrow selfishness, however, which might be engendered in one of this most intelligent class, by dwelling upon the idea that "I am holier than thou," is soon dispelled when he comes to see that no man lives entirely to himself alone; not only is each person to some extent his brother's keeper, but he is dependent on all about him for immunity from dangerous communicable disease, and for safety of life and health in various ways.

The highest selfish interests thus join with the highest benevolence in favor of the widest possible diffusion of sanitary knowledge, and of the most complete obedience to sanitary precepts, ordinances and laws.

INCREASE OF THE PUBLIC-HEALTH SERVICE, AND OF SANITARY PUBLICATIONS.

An important factor in sanitary progress is the increase in the number of persons who enter, more or less permanently, upon some branch of sanitary work. In many of our States such increase is very great. For instance, in Michigan when the State Board of Health was organized, in 1873, there was hardly an active local board of health in the State; very few local health officers were appointed; while for the year 1887-88 over thirteen hundred local health officers were appointed in the State, and many of them physicians who devote considerable time to the work.

The increase in the numbers of our people who live in the cities and villages, the improvements in plumbing and other sanitary appliances, the increasing tendency toward sanitary inspections

¹ The time allowed. Jour. Am. Med. Assoc., June 25, 1887, p. 715.

of such appliances, with the increased number of health officers and sanitary officials, and the greatly increased public interest in sanitary affairs, has built up a class of sanitary and trade journals, which do much for sanitary progress. Many physicians are now or have been health officers. For this, and other reasons, the medical journals seem to contain an increasing proportion of literature bearing upon sanitary administration, and other branches of State Medicine.

But the most important factor tending to increase the demand for sanitary literature is the work of the boards of health themselves, and especially that part of their work which consists in spreading among the people, in popular pamphlet form, the existing knowledge applicable to the restriction and prevention of the most dangerous diseases, including the relations of low ground-water and of contaminated water to typhoid fever, and similar information of immediate practical utility. This work is productive of immediate good in the reduction of the sickness and mortality from such dangerous diseases; and it stimulates a general desire among the people for more knowledge on such vital subjects.

The apparent popular demand for sanitary literature is being met by several of the State Boards of Health, by the publication of a monthly journal which serves as the organ of the State Board which issues it, and as a convenient means of regular communication between the office of the Board and the health officers and others throughout the State who are interested in public-health work. Such a journal is now published in Minnesota, Maine, Pennsylvania, Tennessee, Ohio, Iowa, and perhaps other States. In some of the States the proceedings of the State Board are published quarterly, and distributed quite generally within the State.

ORGANIZATION.

The increased number of persons in the public-health service, with the growing general interest in their work, prompts organization for comparison of methods of work, for coöperation wherever practicable, and for the general promotion of sanitary affairs.

In some of the States this tendency has led to the formation of Sanitary Associations, consisting mostly of physicians and others of the leading thinking classes. The Ohio State Sanitary Association is a notable example; but Associations have been formed in other States. The principle involved is not quite the same as in the "Associations of Medical Officers of Health," in England and in the Province of Ontario; but inclines more toward the popularization of sanitary information and measures among the people generally than toward the advancement of the knowledge of the medical officers of health. The as-

sumption (which is probably correct) seems to be that the medical officers of health are now in advance of the people, and do not, so much as the people generally, need to advance their knowledge of sanitary science or of sanitary administration. However, under the system of free and general distribution of the best that is known, by State Boards of Health, it would seem that the time is near, when, throughout this country Associations of medical officers of health need to be formed, for their own advancement, and for the best interests of sanitary progress.

In Michigan, and some other States, although local Sanitary Associations have been formed, sanitary conventions have, thus far, been the principal method of popularizing sanitary measures. The topics chosen have reference to the the greatest apparent needs of the locality in which the convention is held, such, for instance, as the present methods of disposing of excreta and waste products, and the present source and condition of the water-supply of the city or village, including the exact relations of privy-vaults to wells in the principal business part, and the principal residence portion of the place, and the explanation of the best means for restricting the most dangerous communicable diseases.

These practical questions of vital importance can be so presented by members of State Boards of Health, by leading physicians, lawyers and ministers, and so impressed upon the people of almost any community that thereafter much greater attention will be given to affairs which relate to the public health.

THE NATIONAL CONFERENCE OF STATE BOARDS OF HEALTH.

The increasing intelligence of the people is now tending to stimulate progress by those who aim to lead the people in State Medicine. The most notable organization of this nature within recent years is the Conference of State Boards of Health, a National Association of delegates from State Boards, but having international tendencies, as shown by the fact that it includes delegates from the Provinces of Canada. It has had its fifth annual meeting in Cincinnati, just preceding this meeting of the American Medical Association. It does not supplant the older American Public Health Association, which aims at the popularization of sanitation, and for the advancement of sanitary science, but its work differs from both these functions of the older Association, being largely concerned with the practical questions of official public-health work, and its membership is restricted to officers who represent those who can put in force the conclusions reached by the conference. It is a league which, to some extent, serves to unify the Public-health Service of the United States, and might be utilized in the same direction to a much greater

extent by the United States Government, to supply the lamentable loss of our National Board of Health, or to coöperate with a National Bureau of Health, or with a National Board of Health, should the present Board, or a new one be granted an appropriation.

LEGISLATION: LOCAL, STATE, NATIONAL.

Sanitary laws are commonly supposed to have two functions: if properly published and enforced, they are educational; and they may be enforced in cases where no other course will secure obedience to sanitary precepts. But sanitary laws have other functions. A new general principle of sanitation, before suggested, is important especially in connection with sanitary legislation. According to this general principle of action it would seem that for the interests of sanitary progress, the most important legislation is that which provides for the collection of facts, not only those upon which to base immediate action, but also those out of which to construct sanitary science, that which provides also for the comparison and study of those facts by persons especially qualified for that service, and for the publication of the results of such statistical and other researches for the benefit of all classes of people. The facts necessary for immediate action are as imperatively needed as is the knowledge of the location of a burning building, and for much the same reason—in order that the danger may at once be averted. And, as in the case of a dangerous communicable disease, life and health as well as property are at risk, any ordinary pecuniary interest of the individual should yield to the high moral duty to the public safety, and await recompense from the public. Therefore I agree with Dr. Rohé, our chairman last year, who said: "The *first* requirement then in dealing with infectious diseases from a 'State Medicine point of view' is *notification*, and inasmuch as such notification will never be effected if voluntary, it must be made compulsory.

"The *second* requirement in restricting the prevalence of such diseases is the segregation of patients, and guarding healthy individuals except the immediate attendants, from contact with them.

"The *third* requirement is prompt and thorough disinfection, in other words, the absolute destruction of the infective properties of infectious matter, in whatever that may consist.

"I would therefore declare the watchwords, of the practical and progressive sanitarian in dealing with communicable diseases, to be these three: *Notification, Isolation, Disinfection.*"

There seems to be progress in the first essential (notification) in many parts of the country. In England the area of country coming under that law is increasing, and it is proposed by the local government board² to extend the system of com-

pulsory notification, and perhaps to make the law general, although in that country there has been opposition by some of the medical profession. In Michigan notification of dangerous diseases is compulsory upon householders and physicians, and physicians are allowed a very small fee (ten cents) for each case reported. Only small-pox, diphtheria, and scarlet fever are specifically mentioned in the law, but several other diseases including typhoid fever, and *rötheln*, have been declared to be "diseases dangerous to the public health." Increasing attention to this subject is noticeable in Michigan, in Wisconsin³, in Minnesota, in Maine,⁴ in Iowa,⁵ in Indiana,⁴ in Kentucky.⁴ In New Hampshire, also, a law has been enacted requiring physicians to report all cases of diphtheria and scarlet fever to the local board of health.⁵

STATE LEGISLATION: PROTECTING THE PURITY OF INLAND WATERS.

The last general court of Massachusetts made an appropriation of \$30,000 for the use of the State Board of Health in protecting the "purity of inland waters." "It was thought wise to begin with the largest and most important supplies." . . . "From time to time other water supplies have been examined in this exhaustive manner." . . . "Four rivers in the State have been systematically examined." The results of these examinations are given in the report of that State Board, made January, 1888. The Board has established an experiment station, to determine the amount of sewage that can, in that climate, be purified by application to different soils.

LEGISLATION: NATIONAL.

That the United States Government pays less attention to those highest earthly interests of its citizens—human health, and life itself—than other governments, and even less attention than it gives to the protection of the swine and other domestic animals, is a cause for regret and shame to all intelligent citizens, and especially to physicians, because their attention is so frequently called to the subject, and because they realize how much might be done for the prevention of epidemics, and, more especially, of the sickness and deaths from the most common causes.

As usual, there is now before Congress a bill for a National Health Service.

WHAT PREVENTS NATIONAL LEGISLATION IN THE INTERESTS OF PUBLIC HEALTH.

A brief review of some of the efforts of physicians and Associations may aid to a clearer understanding of the situation.

Fifteen years ago in this same City of Cincin-

² Circular issued Dec. 5, 1887. Published in "City of York, Report on the Compulsory Notification of Infectious Diseases, York, Eng."

³ Sanitary News, Jan. 28, 1888.

⁴ Sanitary News, Feb. 4, 1888.

⁵ Sanitary News, Feb. 11, 1888.

nati, May 1, 1873, I listened to a report to the American Public Health Association made by C. C. Cox, M.D., LL.D., of Washington, on "The Necessity for a National Sanitary Bureau." The report, and the "Bill to establish a Bureau of Sanitary Science" which had already been presented to the U. S. Senate, are published in Vol. 1, pp. 522-532 of the Transactions of that Association.⁶

Dr. Cox said: "Regarding the continually increasing sanitary wants of our country . . . it occurred to me that our government should advance among the first to conserve the health of its population, and avert the disasters which menace it. With this view I prepared, in 1871, the plan of a National Bureau of Health. This was subsequently submitted, as you are aware, at a meeting of the sanitarians, representing the different sections of the country, assembled at New York, and endorsed by them in a series of commendatory resolutions."

After the reading of the report by Dr. Cox, the American Public Health Association adopted a resolution "that in the judgment of this Association, the establishment of a National Sanitary Bureau, with relations to the general government similar to those of the Bureaus of Agriculture and Education, is highly desirable as a means of promoting sanitary science and the protection of the public health."⁶

November 14, 1873, at the meeting of the American Public Health Association in New York, resolutions presented by myself were adopted,⁷ favoring the project, and for the appointment of a committee representing, so far as practicable, each State in the Union, to memorialize Congress, and to coöperate with a similar committee or "section" of the American Medical Association. Through the belief of the President of the Health Association and others that the time was not favorable, the effort was not vigorous, and it was unsuccessful at that time.

November, 1878, at a meeting of the American Public Health Association in Richmond, Va., I again presented resolutions outlining proposed duties of a permanent U. S. Health Commission, proposing a committee of the Association to memorialize Congress for the establishment of the Commission, and for the appointment of a standing committee on Public Health in each legislative branch of the U. S. Government. The yellow fever epidemic of that year emphasized the need for some action by our government. The Association committee was appointed, nearly every State being represented upon it. Dr. Billings, of Washington, was especially active. Hon. J. H. McGowan, a member of Congress from Michigan, was induced to confer with Dr. Billings, introduce a bill, and labor for its passage. The Na-

tional Board of Health was thus established. For a few years it did excellent work, which was commended by the leading sanitary associations in this country. It had the respect and confidence of nearly every sanitary authority in this country; but, from the first, it had the determined opposition of a few who were in office and power in Washington, and who were eventually able to cripple and finally to defeat appropriations for it by Congress. The distinguished sanitarians who were its first members dropped out, and to-day the Board exists only in name.

In a recent number of the *New York Medical Journal* is an editorial entitled "The Marine Hospital Service and the Proposed National Bureau of Health," in which is an account of the arguments recently before a committee of Congress for and against the proposed legislation. The arguments for it were mainly by the President of the National Conference of State Boards of Health, and by three ex-presidents of the American Public Health Association, a committee representing the principal sanitarians and sanitary organizations of this country. The only opponent mentioned was Dr. Hamilton, of the Marine Hospital Service, who "submitted a brief." The editorial says: "Under one form or another, the old National Board of Health has been sought to be revived on several occasions, and each time Dr. Hamilton has had to oppose the attempt almost single-handed."

Officers in the medical departments of the army and navy, on the other hand, have favored the National Board of Health or other public health legislation; but it is much easier to prevent than to obtain appropriations.

FOR WHAT PURPOSE ARE WE HERE?

In order to fulfil the duties assigned to me, I have studied again the apparent intention of the founders of this Section, and of those who have contributed to its maintenance. It would seem that there has been and is in the medical profession a profound desire to promote the general welfare by utilizing for the public good those vast stores of scientific and practical information gained by the medical profession, which, although not of much use in the *treatment* of disease, are capable of a much more important service in the *prevention* of disease. I think there is a growing belief that there is a higher plane than even the exalted one on which the medical practitioner has long stood, and that if quite a large proportion of the medical profession were employed and paid for their efforts for the prevention of disease, their relations to the people would be of the noblest kind. The methods which tend in this direction are those which seem to have actuated the founders of this Section—those which favor the formation of State and other Boards of Health, and (as the

⁶ Pub. Health Trans. of Am. Pub. Health Ass'n, vol. II, p. 537.
⁷ Page 543, vol. II, Pub. Health Trans. Am. Pub. Health Ass'n.

name of the Section, "State Medicine," implies) build up the legal organizations, local, State, and National, through which only can the public reap the results of the progress in sanitary science.

But those of us who have watched the progress of this Section know that although the Section has almost uniformly held back from recommending specific legislation, sometimes even discouraged attempts at public health legislation, it has always favored that other essential to progress in this direction, the building up of a sound sanitary science for the use of the State, whenever the State shall become sufficiently intelligent to utilize it.

Nearly all the papers and discussions before this Section are expected to contribute to this scientific branch of our work; therefore, if numerous important lines of work in the sanitary sciences, during the past year, are not mentioned in this address, they are likely to be brought out during this meeting, especially those relating to the topics especially chosen, "Malaria and the Causation of Fevers." There has been considerable progress in the knowledge of the causation of fevers, but a satisfactory mention of the lines of work would take too much of the time allotted to this address.

DEVELOPMENT OF THE GERM THEORY OF DISEASE.

Progress seems to be in waves, and greatest along certain lines. Recently many have been engaged in investigation and experiment in developing the germ theory of disease. Great progress has been made, considering that it has been largely the contributions of individuals; for as a rule those for whom this work is most valuable—the common people themselves—have not yet awakened to the importance of such work so as to demand of their representatives that it shall be maintained by the governments. The Imperial Government of Germany has wisely maintained the laboratory in which Dr. Koch's great contributions to science have been taught to large numbers from many countries. In this country the General Government has done little worthy of special notice, but individual officers, in several branches of the U. S. Service, have contributed much toward progress in this direction, notably Dr. Sternberg, of the Army Medical Department.

A writer in *Science*⁹ has lately published results of an inquiry by circular, addressed to each of the medical schools in this country, asking questions concerning the germ theory, and what is being done about it. Replies were received from those colleges in which the greatest number of students is taught. He concludes that quite a number of bacteriological laboratories have been established in connection with our larger medical schools.

They are under the charge of competent directors, and are places where original research is being carried on, and where students have an opportunity to familiarize themselves with the subject in a practical manner. American medical schools are thus doing their share in this research in this manner, and the endeavor to advance our knowledge of bacteria and their relation to disease.¹⁰

In Baltimore there is a well-equipped bacteriological laboratory under the direction of the Professor of Pathology of the Johns Hopkins University. In Brooklyn,¹¹ the Hoagland Laboratory—the gift of Dr. C. N. Hoagland—under the immediate supervision of that gentleman, who provided the funds for the building and its equipment, "will supply all the facilities, both for students and for advanced investigators, which can be found in the best-equipped laboratories of Europe."¹²

In Missouri the Legislature has appropriated \$5,000 for "the creation of laboratories for bacteriological study and investigation, and for the culture of vaccine virus, in connection with the State University at Columbia."¹³

A STATE LABORATORY OF HYGIENE.

In Michigan, the Legislature has appropriated \$35,000 for the building and equipment, at the State University, of two laboratories, under one roof, one being a laboratory of hygiene. The building will be ready for occupancy next October. Dr. V. C. Vaughan, Member of the State Board of Health, and Professor of Hygiene in the University, is Director of the laboratory.

Prof. Vaughan's first Quarterly Report of work (the chemical laboratory being temporarily used) has been published by the Michigan State Board of Health,¹⁴ and includes a history of important contributions to sanitary science. He has isolated the Eberth bacillus of typhoid from water believed to have caused that disease, he has caused a disease resembling typhoid by injecting these bacilli into an animal, and has caused a rise of body temperature in animals by injecting a ptomaine, formed by those bacilli, but sterilized before its use. Dr. Vaughan has been able to find these bacilli in the air of a house-drain into which discharged a soil-pipe carrying discharges from a typhoid patient. He has made cultures of the bacilli there found. Other cases of typhoid fever had apparently been caused by the inhalation of air contaminated by emanations from that same house-drain.

A SPECIFIC CAUSE OF TYPHOID FEVER.

That filth alone will not cause typhoid fever, in the absence of the specific cause, is constantly becoming more evident. A notable instance is given by Dr. F. H. Blaxall, R.N., in the *London Practitioner*.¹⁵ An outbreak of typhoid fever oc-

curred among persons using water from a spring which, although known to be badly contaminated by excreta, had been used without causing typhoid fever for a period of fifteen years; yet soon after the arrival of cases of typhoid fever in the vicinity of the spring, 36 families were invaded, with some 80 cases of recognized typhoid fever, 8 proving fatal. All the persons attacked had drunk of the water from the spring. In this instance, the disease was not communicated from person to person, nor to persons who used the same water-closets as did those who had the fever.¹⁵ This evidence is especially of importance as to the protection of the water supply from typhoid excreta, and of the disinfection of all excreta from typhoid patients.

BACTERIA AND SUMMER DIARRHŒA.

Results of experiments and bacteriological observations in summer diarrhœa have been published.¹⁶ Many bacilli were studied, but one chief bacillus, which was found, somewhat resembled that of Asiatic cholera, but is shorter and thicker. Cultivation of bacilli from air from sewer ventilators showed some which resembled those found in the organs of persons dead from diarrhœa, but they were much slower in their growth. Those from the intestines developed rapidly, liquefied jelly became alkaline, and bacilli of the fifth generation emitted a powerful odor of decomposition. A very small dose of the artificially cultivated microbes produced a smart attack of diarrhœa.¹⁷

ALBUMINURIA FROM SEWAGE POISONING.

Dr. George Johnson, in the *Brit. Med. Jour.*, March 13, 1888, "directs attention to the fact that among the many causes of blood contamination and consequent albuminuria, sewage poisoning is by no means an infrequent one."¹⁸

BACTERIA IN CEREBRO-SPINAL MENINGITIS.

Fränkel, Weichselbaum and others, in a series of cases of primary cerebro-spinal meningitis, have obtained pure cultivations of Fränkel's pneumococcus¹⁹ which, I suppose, is the coccus first discovered by Dr. Sternberg, in his saliva, (*Micrococcus Pasteuri*, Sternberg), and which is fatal to rabbits, and has been found in pneumonia more frequently than other microorganisms. Weichselbaum has also described a new coccus in six cases of idiopathic cerebro-spinal meningitis.²⁰ Dr. F. Goldschmidt has reported the same microorganism in one case;²¹ and Dr. Biggs, of New York, in one case, found a diplococcus probably identical with the one described by the other two observers.²²

THE SPECIFIC CONTAGIUM OF SCARLET FEVER.

That there is a specific contagium of scarlet

fever is not doubted now, I suppose, by any intelligent physician; but just what that contagium is has not yet been satisfactorily proved. The results of Dr. Klein's investigations into the subject, in connection with the Hendon cow disease, supposed to be scarlet fever in the cow, have been strongly combated.²³

Experiments by Dr. Edington, of Edinburgh, (made at the suggestion of Dr. Jamieson,) carried on with bacteria from the blood, organs, and skin in different stages of scarlet fever, revealed one bacillus constantly present in the blood before the third day of the fever, and in the desquamating scales after the twenty-first day. This he concludes is the contagium of the disease.²⁴

DIPHTHERIA IN MAN AND ANIMALS.

Dr. Turner's report to the Local Government Board,²⁵ in England, in 1887, collected what was known on the subject of diphtheria in animals. Instances were given of its spread in pigeons, in fowls, and afterwards to families of persons, among swine, horses, cats infected from man and man from cats, successful inoculation of cats, and the occurrence of diphtheria among shepherds after the disease had prevailed among sheep. Bacteriological studies of diphtheria have led Loeffler to conclude that the bacillus is different in the calf and in the fowl, and still different in man.²⁶ Such discrepancies remain for further investigation. Probably much knowledge, useful for the saving of human life, might soon be worked out if the people would maintain more workers in this field of investigation.

SUPPURATION ALWAYS DUE TO MICROÖRGANISMS.

A FUNCTION OF THE LEUCOCYTES.

Although migration of leucocytes occurs under a variety of conditions and circumstances, the general principle that suppuration is always due to the action of microorganisms seems to be established.²⁷

A recent writer has said:²⁸ "There seems to be but little doubt that there exists a constant relation (as regards several of the infectious diseases certainly) between the amount of suppuration and the degree of immunity that different animals show to the respective diseases. The greater the emigration of leucocytes the greater is the insusceptibility, and *vice versa*, the leucocytes apparently destroying, or counteracting the effects of, the microorganism. Suppuration thus comes to be a conservative process, protecting the system from the action or entrance of the microbes. Perhaps this is always its function."

At any rate, knowledge of the relations of the white corpuscles of the blood to the specific mi-

croörganisms of disease seems to be progressing.²⁴

PERIOD OF INCUBATION.

Some experiments by Prof. Vaughan, of the Michigan State Board of Health, indicate that the length of the period of incubation of typhoid depends much upon the number of specific bacteria taken into the body, and whether or not a communicable disease shall be contracted may depend upon the quantity of the specific cause which gains entrance to the body.

DIAGNOSIS OF CHOLERA IN DOUBTFUL CASES.

Further evidence of the practicability of aiding the diagnosis of cholera in doubtful cases, by cultivations of the microörganisms from the intestines or the excreta, has been supplied by Drs. S. T. Armstrong and J. J. Kinyoun, of the U. S. Marine Hospital Service, and Drs. H. Biggs and T. Mitchell Prudden, of New York.²⁵

CAN CHOLERA BACILLI REPRODUCE IN WATER OF NEW YORK BAY?

The salt water in New York Bay has been "Sterilized and inoculated with pure cultivation of the spirilla of Asiatic cholera and also of Finkler and Prior," by Dr. J. J. Kinyoun, of the U. S. Marine Hospital Service,²⁶ with the result that "These spirilla have not only been kept alive, but have also greatly increased in numbers."²⁶ The inference is published that "If dejecta from cholera patients should be thrown into the lower bay, cholera could gain a foothold on the contiguous shores where every condition favorable to its development and propagation sometimes exist."²⁶ The temperature at which the cultivation was maintained is not reported; neither is the temperature of the water at the shore in the most dangerous season, but if there is a probability that such development can occur there, further experiments and observations of temperature will be awaited with great interest, because of the practical importance of the subject, for the safety of this country from cholera.

QUARANTINE.

There has apparently been great progress in keeping certain diseases out of this country by means which we yet call quarantine. Formerly yellow fever was so frequently introduced into New Orleans that many believed it was endemic there; and cholera was generally brought into this country whenever it was prevalent in Europe. Now both of these diseases are kept out. The great money losses to trade in New Orleans have tended to aid sanitarians in perfecting the quarantine at that point. Under the able leadership of that brilliant sanitarian, Dr. Joseph Holt, the quarantine at New Orleans has been brought to a high state of perfection. Perhaps the best evi-

dence of the possibility of general progress, however, is the general criticism of what has heretofore received no attention. As an offset to the criticism of the quarantine system at New York, it should be noted that during the last year that port of New York has been tried—cholera was brought to it, and, so far as is now known, it was not allowed to gain a lodgment. Aside from speaking well of a bridge that allows one to cross in safety, there are other considerations which should make us slow in trying to displace State or local quarantines; there are vast State and local interests in trade and travel which should join with the interests of public health in building up and improving local quarantine administration. Thus far, the United States Congress has not exhibited such a steadfast purpose to guard the lives of the people as to inspire confidence in the United States Government as the best and only protector of the lives and health of the American citizens. Just now there seems to be those who urge that the National Government shall gain control of *all* quarantine. Without considering the constitutional objections, it seems to me that it will be much safer to hold fast to that which we have, at least until such time as the National Government shall demonstrate its ability to do as well. What is really needed is that the local quarantines shall be perfected; that the National Government shall *add* its best services to those of the States and localities;²⁷ and that those other dangerous communicable diseases, diphtheria, scarlet fever and typhoid fever, which cause much more sickness and deaths than do yellow fever and cholera, shall also be excluded by quarantine. If it be argued against this plan that those diseases are endemic, it may be replied that before its exclusion yellow fever appeared to be endemic; and small-pox is still, yet we try to exclude it, and undoubtedly save thousands of lives thereby, and might exclude it almost entirely by more perfect methods.

YELLOW FEVER.

If, as reported, yellow fever is now present in Florida, there is cause for alarm which should lead to extraordinary efforts to limit that dread disease, because it is early in the season, there is no State Board of Health in Florida, and the inspection of travel, isolation of infected persons, disinfection of all infected articles—those measures which constitute the new "quarantine"—are not easily enforced, and in inland places can be avoided by those familiar with the locality. Nevertheless, these measures are the most promising yet suggested.

SMALL-POX.

Since January 1, 1888, small-pox has been reported in twenty-one States of this Union.²⁸

²⁴N. Y. Med. Abstract, March, 1888, p. 56. Also Lectures by Prof. Ray Lankester, Sanitary News, Chicago, April 21, 1888.

²⁵N. Y. Med. Jour., Nov. 12, 1887, pp. 546-7 and 548-9.

²⁶Sanitary News, Feb. 15, 1888, p. 188.

²⁷There is now a bill before Congress to improve the National quarantine, which it is hoped may become a law. It has passed the U. S. Senate.

²⁸Maine, Massachusetts, Rhode Island, Connecticut, New York, Pennsylvania, Delaware, Ohio, Kentucky, Indiana, Illinois, Michigan, Wisconsin, Minnesota, Iowa, Kansas, Colorado, California, North Carolina, Tennessee and Louisiana.

Small-pox is now reported in nine States as follows: Connecticut, California, Colorado, Illinois, Kentucky, New York, Minnesota, Pennsylvania and Wisconsin. Although small-pox is still (or was recently) present in nine States, it is not spreading, and it speaks highly for the utility of the public-health service generally throughout this country that although introduced into twenty-one States of the Union, small-pox has not been allowed to spread to any great extent, except in California, where its restriction, on account of the Chinese, was especially difficult.

CHOLERA SHOULD BE MADE A DISEASE OF THE PAST.

Dr. W. J. Simpson, Health Officer of Calcutta, has reviewed, in the *Indian Medical Gazette*, the evidence as to the influence of season, rain-fall, and water-supply upon cholera, accepting the evidence brought out by Dr. Payne²⁹ and elaborated by Dr. O'Brien,³⁰ that in Calcutta the cholera was greatly reduced by the improved water-supply, and the evidence collected by myself that it was greatly influenced by the rainfall,³¹ and he has added much to the completeness of these converging lines of evidence. Dr. Simpson says: "In the common condition of polluted wells and tanks, and the habits of the people, we have an explanation of seasonal cholera prevalence in Calcutta, synchronous with cholera prevalence in the neighborhood, while the increased scarcity of water in the town during the last five or six years, culminating in such expedients as underground tanks for collecting water which ought to reach at least the first floor of the houses, we have a fair explanation of the increased cholera prevalence of late years in Calcutta, out of proportion to the period between 1870 and 1880." Speaking of the effect of the rains, he says: "They purify the air, they wash the filth from the soil, they purify and give an abundant supply of water to the wells and tanks; but, in addition to these things, in the town they perform a most important function, they flush the drains." Dr. Simpson closes his forty pages with these words, "A study of the distribution, progress, and seasonal changes indicates that the chief factor is want of pure water."

Elsewhere I have suggested that "If the prevention of cholera in its home is so largely dependent upon the rainfall and upon a good water-supply, one direction is thus indicated for most successful efforts for its prevention in this country."³²

Here I wish to suggest that, inasmuch as all the cholera throughout the world is derived from the small endemic area around Calcutta, the nations of the earth might well undertake an inter-

national work for doing away with that "chief factor" of cholera prevalence in the endemic home of cholera, namely, that "want of pure water." Two-thirds of the cholera mortality in Calcutta has once been stopped in that manner.³³ The inference is plain that the other third might be stopped by more thorough but similar means, and if in Calcutta then also in the area around Calcutta. The work would be difficult, partly because about Calcutta the ground-water is brackish, but I believe the scheme is entirely practicable. It would be a noble mission to accomplish this, and, as an international work, it would "pay" in dollars and cents.

PURIFICATION OF WATER BY CHEMICALS.

Progress has been made in our knowledge of methods of improving public water-supplies. The practice of adding a minute quantity of alum to water in order to clarify it, is an old and very familiar one. Recently one method of applying it continuously to public water-supplies has been patented. Prof. Albert R. Leeds, of Hoboken, N. J., added alum, in the proportion of half a grain to a gallon of water, and found, with the precipitation of peaty matter, etc., a reduction of the bacteria to such an extent that whereas before precipitation it contained 8,100 colonies per cubic centimetre, after precipitation the supernatant water contained only 80 colonies. They were all the bacterium *lineola*, and by filtering this supernatant water through a double thickness of sterilized filter paper into a sterilized tube, he found no bacteria in the filtered water.³⁴ An interesting question is, whether or not the bacteria of typhoid fever would be removed by this same agent in a similar manner. Prof. Leeds suggests the addition, also, in certain cases, of lime or soda, or a minute amount of soluble iron salt, like ferric chloride, and its removal, together with the bacteria, by filtration.

VITAL STATISTICS.

Vital statistics supply an important basis for public-health work. We are dependent upon mortality statistics for our knowledge of what are the greatest dangers to life, and of what progress we are making in the prevention of deaths. Although the importance of vital statistics is well known to sanitarians, it is not yet appreciated by the people generally; and the practical work with statistics is so difficult that comparatively few master the general principles. There are no journals or ready means of comparison of views among statisticians; therefore progress is slow, especially in laws for the collection of vital statistics. Yet there is progress toward the collection and the improvement of some statistics in this country.

³⁴The Medical News, Phila., Sept. 3, 1887, p. 262.

In Minnesota, Dr. Hewitt, Secretary of the State Board of Health, has within the past year effected considerable in this direction. In the Connecticut State Board of Health Bulletin for February, 1888, Dr. Lindsley, Superintendent of Vital Statistics, says: "For the first time since these monthly bulletins have been issued, reports have been received at this office from every town in the State." The last quarterly report of the Illinois State Board of Health says: "For the first time since the collection of vital statistics was begun, all the counties have made returns of births and deaths."

SICKNESS STATISTICS.

For some purposes, including those of immediate action for the restriction of dangerous diseases, reports of sickness are much more valuable than the reports of deaths. An account of the methods successfully employed for several years in Michigan was given before this Section last year. Those methods are being continued in Michigan, and the State Board of Health of Ohio has established methods somewhat similar, which promise very useful results.

THE ETIOLOGY OF DISEASES.

Sickness statistics are especially valuable in studying the causation of diseases. The sickness is nearer than the deaths are to the time of the causation of the disease. The statistics of sickness and meteorology in Michigan have proved that most of the important diseases are controlled by conditions of the atmosphere. Even such diseases as small-pox and scarlet fever, due to specific causes, have close relations to the coldness and dryness of the air inhaled. This knowledge does not antagonize the importance of isolation and disinfection in such diseases, but it shows why these measures are especially important when the air is cold and dry; and, inasmuch as the virus of those diseases clings for a long time to infected articles, it explains why, unless disinfection is enforced at all times, these diseases tend to break out and spread during the cold seasons of the year. The explanation is found in the fact that nearly every one of the diseases of the throat and air-passages is increased after the inhalation of cold dry air. Communicable diseases which enter by way of the air-passages thus find at such times a most easy entrance. Consumption is found to follow the same law, increasing after the cold dry season of the year, and decreasing after the warm moist season.

It appears, therefore, that there has been great progress in our knowledge of the relations of sickness to meteorological conditions, so that, in Michigan at least, we are now able to say under what meteorological conditions each one of many of the most important diseases will increase or decrease in prevalence. The times, or at least the conditions of the rise and fall of the sickness

from these diseases³⁵ can be predicted in advance with almost as much accuracy as can the recurrence of the seasons. This may seem to you like laying claim to one of the grandest of recent human achievements, but I think the statement is strictly true, and this knowledge of the conditions tending to the occurrence of diseases, should aid us greatly in the adoption of measures for their prevention.

THE PRESIDENT'S ADDRESS BEFORE THE AMERICAN RHINOLOGICAL ASSOCIATION.

Delivered at the Annual Meeting, Cincinnati, Ohio, September 12, 13, and 14, 1888.

BY CARL H. VON KLEIN, A.M., M.D.,
OF DAYTON, OHIO.

FELLOWS OF THE AMERICAN RHINOLOGICAL ASSOCIATION:—Under the present system of modern organizations, be it a political government, a commercial or scientific organization, be it ever so small, it is demanded from the head of such government, or such commercial or scientific organization, to deliver an annual message or address. A duty which I am called on to fulfil, regardless of my ability, and probably my errors recorded for generations to come; for words are like milk, which, once being drawn from its original source, can never be returned again. At this age of remarkable discoveries and wonderful developments in science, one might not at ease deliver his sentiments without fear that some one will reply to his errors, as times are not as they used to be. Three hundred years ago, could a person have been put to sleep and have continued in that state fifty years, on awakening and returning to the schools of medicine, he would have found the same textbooks, the same mode of teaching, the same elements of thought, perhaps without a single change.

Now, let a person remain in seclusion for not more than five years, on returning he would find many changes in the teaching and practice of medicine. For medicine in this century comes and departs with the fashions of garments, many have died with the Grecian bend, and as many more will die with the present mode of the posterior phenomena. The continual shifting in theoretical medicine gives a theory, but a short lease of life. A new theory established to-day, after laborious and tedious experiments, discarded to-morrow. Fruitful as has been the present age in changes of medicine, yet can any one of our medical colleges boast of a professor's chair on Rhinology? In many it is so entirely unknown,

³⁵ Influenza, tonsillitis, bronchitis, pneumonia, croup, diphtheria, scarlet fever, small-pox, consumption, remittent fever and typhoid fever. Tables and diagrams proving this, relative to some of these diseases, are published in Trans. Int'l Med. Cong., Washington, D. C., 1887.

that it is not even regarded as an object of secondary importance.

The Talmud relates that Rabbi Huna once asked his son why he did not attend the medical lectures of Rabbi Chisda? "Because," replied the son, "he only treats of temporal and wordly concerns." "What," said the father, "he occupies himself with that which is necessary for the preservation of human beings, and this you call wordly affairs!" Trust me, this is among the most estimable of studies. I will as well say to those who consider Rhinology of a minor importance that it is the most worthy study in the science of medicine. With the complete modern scopic inventions one cannot but help to progress in the investigations of diseases, and discover afflictions through the rhinol cavities diseases of other organs.

The rhinoscope brings before us stupendous facts which we are called upon to observe in our daily practice, which gives advantages in treating diseases of more obscure cavities, and lessens the suffering of the human race, and improves the health of many who are by nature predisposed to inroads of hasty death.

I must confess that I am unable to understand how a physician can treat a disease in which he received no instruction, and how a profession like ours intended self sacrifice to devotion or relief of human suffering could be guilty of empiricism. I consider those who treat diseases for which they are neither qualified nor prepared empirics, however conscientious and faithful a follower he may be of the catalogue of diseases contained in his symptom book. Yet I hold it dishonest if he tampers with that to which his eye is neither trained to see nor his hand to perform.

No branch of the healing art has, indeed, been marked with more empiricism than Rhinology; she struggles against far greater difficulties than any other branch of specialistic medicine, for both ignorance and prejudice have lent their aid toward retarding its advancement. It is a common thing for a traveling imposter to announce himself to the public as a catarrh specialist in addition to being a specialist of all other organs of the human body, while the regular practitioner as well, with his bulb spray, is ready to make fifty cents whenever he can, regardless of his brother's toil, and all his brother has learned by sacrificing with midnight oil to the knowledge of modern medicine.

As long as a physician brings his wisdom into market as an article of commerce, we cannot expect from him but to do anything for a remuneration, he will undertake to treat disease, even if he knows that he is deficient in that branch. There are many specialists who are pernicious to their class by dealing with their specialty like a merchant, who tries to sell other goods if he has not the article you call for. If you will ask him

for satin, which he has not in stock, he will aim to sell you silk; just so with dishonest specialists. They will try to make their patients believe that the disease of the organs afflicted come from diseases of their specialty, for the sake of gaining gold, which has always been a snare to men. Oh, gold! Chief source of hills, corruptor of life, that turneth all things wrong!

"Gold breaks through every sacred tie,
And bids a friend or brother die;
The fruitful source of kindred strife,
Gold would not spare a parent's life.
Long wars, and murders, crimes untold,
All spring from the cursed thirst for gold."

Physicians of vicious practice are doubly pernicious, being not only guilty of immoral practice themselves, but likewise of spreading them far and wide among their fellow practitioners, who profess better things. It is equally wrong to treat maladies in which diagnosis cannot be made, as it is to treat patients who apply for treatment of diseases with which they are not afflicted. "To those who are not sick the physician is useless, and the pilot to those who do not sail."

Cicero says: Those are wise monitors who teach us to do nothing of which we are doubtful, whether it is honest or just; for whatever is honest, manifests itself by its own lustre, but doubt implies the entertainment of injustice. Let me not, however, be misunderstood. It would grieve me even to be suspected of the folly and injustice of promiscuous accusation. Believe me that no one is convinced more than I that the medical profession possesses the highest grade of human respect, but there is never a garden ever so beautifully cultivated that has no weeds. The profession to which we belong is not an indolent occupation. Look at its history and study the magnitude and quality of its labors. Why has it done all this? What would it have done if it had not ambition and aspiration and much heart-hunger? Has not the medical profession had to fight its way from the beginning of the history of man? What profession is there that has accomplished anything for which mankind are the better? Every branch of modern science, every field of modern research, every pursuit which has been under the subject of modern study has been cultivated by the medical profession. Look at the authors of every branch of specialistic science, and no one without the title of doctor of medicine, should such a profession be guilty of having within its faculty malevolent fellows, who would be ready to commit any crime by treating suffering humanity for no other purpose but to their coffers fill? Branded with Ovid's description of deceit to whom all fingers point:

"Hither comes the tradesman, having a girdle around his robes, and in a state of purity draws

some of the water to carry it away in a perfumed urn. He sprinkles his hairs, too, with the dripping bough, and in a voice accustomed to deceive, runs through his prayers O, Mercury! or have invoked the great Godhead of Jove, whom I did not intend to listen to me. But give me profits, give me the delight that arises from gain, and grant that I may find it lucrative to impose upon my customers."

Now, wherein lies the remedy? Gentlemen, the only true solution is a thorough medical education. I maintain that no one can receive a thorough medical education, without a thorough academical training, the mind that is trained to academical knowledge is inspired to a nobler and sublime course in life, in righteousness, piety, benevolence, industry, sobriety, equity, and frugality, kindled with aspiration, for a special pursuit in science to whatever calling by nature of human duty he may be assigned to. If the physician possesses an academical knowledge, he will make the boundless science of nature his study, he will aim to enquire from the beginning of the creation of man, and turn every stone to find inscriptions that may be engraved by organic life. He will form exalted ideas of monuments of primeval antiquity, and make use of all antemundios ways that may be conjured from the outmost bosom of the earth, in order to throw a bright light upon development of medicine. Such men can have no other motive than human welfare. And when they read the works of great men which existed in all generations, whose carcasses have long decayed, but their heroic name still lives, then they are kindled with high aspirations and are anxious to become heroes in the conquest of nature. Thorough education make men gentlemen by habit, by custom, by civilization, by law, and by dress. From the history of the infancy of our race unto the present day, developments of trades and arts are emerged from their primitive state to a perfection, by those who devoted their attention to one kind of skill, and made life almost double its value.

Those stupendous facts in which the whole spirit of the 19th century moves is due to a higher grade of education. In this age of multifarious learning, in which the whole spirit of humanity powerfully and wonderfully moves, cannot, as formerly, be overshadowed by ignorance and superstition. Thorough education will dissipate the darkness of empiricism and disloyalty to humanity. The inventions of surgical instruments is the wonder of this generation. Every day we hear of some new design that harnesses a new force, and assists in means of curing disease. The most useful of all of them are the different scopic inventions, and by their aid physicians are enabled to make correct diagnosis which leads to a rational treatment of disease of more obscure cavities. To the scopic appliances

we are greatly indebted for the development of specialties in the practice of medicine, and yet has it not developed charlatans and empiricism? Has not the vaginal speculum been the cause of producing so great an army of gynecologists that 99 per cent. of the young men who graduate in their schools, regardless of their pathy, immediately equip themselves with a chair and a speculum? Has not the rectal-speculum encouraged the so-called pile doctors? And has not the rhinoscope been the means of producing thousands of traveling catarrh specialists, who pretend to see more with their appliances than the ordinary intelligent physician?

"The doctor's optics must be keen,
Who sees what is not to be seen."

Gentlemen, these obstacles may indeed be great, yet, not insuperable, and we should not allow them to daunt our spirit.

I now come to that which to us is the most painful and dearest part of our duty, and on which the spirit of our entire profession is based, and that is charity. We may ask ourselves, might not a subdivision in our profession cause great destruction to the essence of our occupation? Will it not drive from our doors charity patients? It is necessary for a specialist, in order to secure the comforts of life, to charge larger fees for their services than the public has been accustomed to pay general practitioners. This being understood by the poorer classes, might not they fear exorbitant prices, and in all probabilities suffer from painful and dangerous disease before they would venture to consult a specialist. There exists three classes of charity patients:

1. Those that ask charity.
2. Those that are prevented from asking.
3. Those that cannot ask.

The first is the one that justly applies for it. The second are those who are deprived of the liberty of asking, by being in prisons, asylums, almshouses and hospitals; they cannot receive any other treatment than that furnished by the institution. Such institutions generally have physicians who, by their political influence, have mastered the entire science of medicine. The third is the most pitiful of all, and in the pride of charity he suffers the pangs of death; aside of fearing false modesty of exposure, he also dreads rejection to his askings of his fellow men.

Gentlemen, let it be known that we are not specialists for the purpose of gain, but from conviction that the knowledge of medicine is too great a science for one man to accomplish as a whole, and that we are not practicing for revenue only; we are also ready to receive any one that applies to us for charitable treatment. Let not this beautiful passage of the New Testament be cast upon us: "Though I speak with the tongues of men and of the angels, and have not charity, I am become as sounding brass, or a tinkling

cymbal." Those who give charity to suffering for the purposes of fame, is mockery and indignity; he who uses the crown of charity in order to gain, deserves not the name physician. Let our Association become famous not only in the annals of science, but also for philanthropy. Let us not be in a hurry for wealth, let us not immerse ourselves in a simple study of augmenting a fortune and lose the art of reason by deserting the post of a physician. Let us also be specialists in philanthropy. Look at the history of philanthropists, and you will find that they are all specialists in their cause. The immortal Valentine Haug spent his life in philanthropy for the blind; Johannes Falk, the philanthropist for children; Henrich Pestalozzi, the philanthropist of education; Augustus Herman Francke, philanthropist of orphans; Bartholomew de Las Casas, philanthropist to American Indians; John Howard, philanthropist of prisoners; Sir Moses Montifiore, philanthropist of the oppressed by religious persecutions, etc.

The true physician should be the eyes of the blind, the ears of the deaf, the tongue of the dumb, the brain of the imbecile, and the limbs of the cripple.

By following this rule our Association will become prosperous and renowned and conspicuous among men. While our Association is still young, yet it deserves congratulation for its past success for her wonderful work in progress of practical suggestions in rhinological appliances, and of treatment in diseases of rhinology we can congratulate ourselves for opening the broad gates to the obscure cavities of the upper respiratory tract. We can congratulate ourselves for its wonderful development in training and educating the world to the spray method, to the use of absorbent and essential oleates, for the revision of proper pathological nomenclature, for educating the physician to look after the upper respiratory tract, whilst he is making an examination of the entire body, and for calling the attention of the ophthalmologist and otologist to look for turbinated and other processes that might have produced disease of the organs in their specialty. We can also congratulate ourselves for the world-renowned repute, for the wonderful growth of our organization, and more so for the chosen quality of its members.

In conclusion, gentlemen, I will thank you for the great honor you have bestowed upon me by making me chief magistrate of this worthy organization. You may feel assured that no one is more sensitive to its dignity than I. I also thank you in the name of my friends and associates, who feel highly honored by my elevation. Trusting that we will live and prosper to see every one of our Fellows to pass the high honor which I am now about to deliver to some one more worthy than my humble self.

ORIGINAL ARTICLES.

A NEW OTOSCOPE (PNEUMATIC) FOR THE DIAGNOSIS OF MIDDLE-EAR AFFECTIONS UNDER PASSIVE MOTION.

AN IMPROVED TOXILOPHONE. A NASAL SPECULUM.

Read in the Section on Ophthalmology, Otology and Laryngology, at the Thirty-Ninth Annual Meeting of the American Medical Association, May, 1888.

BY SETH S. BISHOP, M.D.,
OF CHICAGO, ILL.

Preliminary to a discussion of pneumatic experiments upon the ear, it will be a natural proceeding to describe the instrument by means of which we may produce and observe the effects of passive motion in the drum.

The pneumatic otoscope which I have devised for the purpose named consists of a small milled cylinder with an ear-funnel of the most serviceable pattern at one end, and an eye-piece containing a lens, around which revolves an adjustable mirror, at the other end. In the side of the cylinder a spacious aperture admits the light to the illuminating surface beneath. At the funnel end of the instrument is a pneumatic chamber provided with a flexible tube ending in a rubber bulb, or a diminutive syringe, or a lip-piece, as one may prefer. Objection might be made to using the lip-piece for producing suction for fear that the air from the external auditory meatus might enter one's mouth, but it cannot do so if the funnel is properly adjusted to the canal, for the air chamber of the otoscope represents many times the volume of the column of air contained in that

part of the meatus that lies between the end of the funnel and the drum. It is necessary to exert only slight suction force to cause excursions of the drum membrane sufficient for our purpose. The tip of the funnel should be covered with a section of the thinnest soft rubber tube, about one inch in length, to insure an air-tight fit into the meatus. If the opening of the canal is very large the rubber tube should be rolled back upon itself, so as to form a shoulder on that part of the funnel which closes up the mouth of the meatus when the otoscope is inserted. The rubber not only secures a perfect adaptation of the parts to each other, but prevents the funnel from pressing uncomfortably against the walls of the canal. If the meatus is very narrow, a small section only of the rubber should be slipped well up on the funnel to form the shoulder, leaving the end free to enter about half an inch. When it is to be employed as an ordinary otoscope, without the pneumatic experiment, the rubber tip need not be slipped over the funnel.

This instrument is the result of a considerable experience with Siegle's pneumatic speculum, improperly called an otoscope. The advantages of the pneumatic otoscope over the speculum are: First, it is self-illuminating, not requiring the aid of a hand mirror, or forehead mirror, the light being accurately focused on the drum; secondly, it affords a magnified view of the drum; thirdly, the object mirror presents a perfect picture of the interior of the ear, and without the necessity of looking through a lens; fourthly, it can be operated in a smaller canal than will admit the speculum; fifthly, the bright reflection of light into your eyes by the glass of the speculum, the black background of which converts the glass into a mirror, can be avoided in the otoscope by the proper and unvarying relations, and the color, of its various parts.

The teaching of otology is much facilitated by means of this instrument in that the instructor may be sure that students are looking upon the field of vision which is being described. Heretofore it has been necessary to bend closely over patients to look through an otoscope while it was being adjusted, then in rising to afford students the opportunity of inspecting the drum, the necessary movements of your body, or of the patient's, would throw the drum out of the field, or darken it, and compel a readjustment of the instrument. These disadvantages made demonstrations uncertain, long and tedious. The object mirror allows the teacher to stand or sit erect by the patient while he takes observations, then by a slight movement of his head only, or by a turn of the mirror, he may allow any number of students to pass in line, each viewing what is being commented upon. If one pays attention to the lighting up of the end of the funnel, as he can do by looking obliquely through the aperture over the

reflector, he may be sure that the drum is illuminated and within sight. This is made practicable by dispensing with the large funnel fixtures that project from the sides of other otoscopes, and that prevent the teacher from knowing whether the drum is illuminated properly or not, except while he is looking through the lens. The advantage of dispensing with the attachment is not diminished in the least by sacrificing any of the brilliancy of illumination. The objection which some physicians have urged against magnifying otoscopes, that they were compelled to look through a lens, is met in this instance, for one needs only to look at a plane mirror to examine the drum and canal. Should it not be desired to use the object mirror, except in demonstration, it can be turned back, or removed by slipping the adjustable ring, to which it is attached, off from the cylinder.

THE PNEUMATIC TREATMENT.

The value of passive motion in the treatment of stiff joints and atrophied tissues is well recognized in general surgery. The application of the same principle to the same conditions in aural surgery is attended with equally beneficial results. But this is a neglected fact, for you rarely see or read of its use in ear treatment. So little has been written upon the subject, as compared with its importance, that no apology is needed for speaking somewhat minutely in respect to the behavior of the drum head and ossicles under such experiments as the following.

In examining and treating the middle ear with the pneumatic otoscope the instrument should be introduced into the auditory canal with the longitudinal axes of both corresponding, just as any otoscope should be placed. If the instrument is correctly adjusted, a slight suction on the rubber tube will cause the little column of air, which lies between the drum and the funnel, to move outward to the air chamber. The examiner is supposed to be inspecting the drum at the same time. If the drum is healthy, he will observe the membrana tympani perform an excursion toward his eye, carrying the handle of the mallet with it, while the triangular light spot changes position as the relative concavity of the membrane changes. Release the column of air and it moves inward again, allowing the drum head, manubrium and light spot to resume their former positions. Press upon the column of air and it moves inward, carrying the membrane and mallet handle with it, causing motion in the joints of the ossicles; the short process projects outward prominently, the light spot changes with the increasing concavity, and the ossicles become more prominently visible as the membrane presses around them. By alternately rarefying and condensing the air in this manner the amount of mobility in the drum head and the chain of bones may be determined under brilliant illumination and magnified inspection. If ankylosis of the

joints of the ossicles, or if bands of adhesions between the bones and the walls of the tympanum exist, the handle of the malleus will be seen to be impeded in its movements, or it may remain fixed, while the membrane about it may be quite flaccid. At this point I wish to anticipate criticism by stating that I have never known any ill effects to follow this line of treatment. If the membrane is greatly thickened in patches, or if it contains calcareous deposits, these portions will be seen to resist the action of the vibrating column of air, while normal parts, and areas of thin cicatricial tissue that indicate the location of former perforations, may respond readily to the experiment. In cases where the drum head is very thick, or where the ossicles are bound down by adhesions to the walls of the tympanum, no perceptible movement may be obtained at first, but decided improvement often follows a persistent use of the pneumatic treatment.

In obstinate cases the progress may be hastened by making pressure directly upon the processus brevis by means of a probe covered with a soft rubber tip. Stiffness in the joints may be overcome in this way so as to facilitate the action of the otoscope. One should press gently on the process until the handle moves, then retract the probe until the malleus resumes its former position, press again, and so repeat the movement several times. Then the pneumatic principle of the otoscope should be applied until one is satisfied that the advantage gained will not be lost. The pressure need not cause pain, but the mallet should be moved until the patient experiences a sensation of movement or of sound. In several patients in whom I have applied passive motion in this manner during the last few months I have increased the hearing-distance for the watch from contact to three, twelve, twenty and thirty-two inches, or one-half the normal distance.

The otoscope may reveal an opaque membrana tympani, so hypertrophied and stiff that it does not yield to the pneumatic treatment. In such a case it is nothing less than a barrier to the admission of sound waves to the perceptive apparatus, and would seem to justify the complete removal of this barrier, when the auditory nerve is not diseased. For if the perceptive apparatus is in condition to do its work, while the conducting apparatus is a hindrance instead of a help, the sooner the obstruction is removed, and sound admitted, the better. It should be understood that this statement is made on the supposition that the condition referred to has proved intractable under the usual treatment. Thus it will be seen that the pneumatic otoscope becomes an indispensable factor in determining the precise condition of an organ so hidden away by nature in a deep recess of the head that any auxiliary to our present helps in diagnosis and treatment ought to be welcome. We are not able without it to judge

intelligently when so delicate and important an operation as resection of the drum head may be necessary as a last resort. And while I am conscious of the strong sentiment of opposition to such operations, I venture to improve this opportunity to urge the occasional necessity and the justifiableness of such an operation, and to invite the most searching criticism of the logic of this procedure.

AN IMPROVED TONSILOTOME.

Any physician who has had a considerable experience in tonsilotomy, with the various tonsilotomes, will not be likely to deny that these instruments are generally too complicated. They are armed with needles, barbs, or sharp-toothed forceps for piercing the tonsil and dragging it through the fenestra before any cutting is done by the blades. A tonsilotome constructed after

the pattern I have made renders the barbs, etc., unnecessary. It reduces the painfulness of the operation by one-half; it divests the procedure of any danger of an accident to the operator or patient; it makes a skilful and easy operation possible with a minimum amount of experience; it resembles a large folding tongue depressor so closely that children usually offer no opposition to its introduction for the removal of the first tonsil; and it combines strength and compactness with simplicity of construction. It is made on the principle of the guillotine, the blade of which is propelled by the thumb of the same hand which

grasps the handle. The latter is set at such an angle to the shaft as will permit the most perfect coördinate action of the muscles of the hand and arm of the operator. All the work may be done with one hand. This advantage is not a small one for two reasons: The powers of coördination and antagonism of muscles are far more perfectly under control in operating an instrument that requires but one hand, than they are when both hands must coöperate; and one hand of the operator is left free to hold the head of the patient, if necessary, as the dentist does in extracting a tooth. The advantages of a tonsilotome that can be operated entirely by one hand are about the same as in a tooth forceps which does not require two hands to manipulate.

I have had two sizes manufactured, the smaller having a fenestra of the calibre ordinarily found in such instruments, the larger supplied with an aperture larger than the largest Mackenzie tonsilotome, while it is so compactly constructed as to require less space in which to operate. I have used the larger size to extirpate enormously hypertrophied tonsils in children as young as two and one-half years, where it was impossible to insert the Mackenzie instrument of the necessary size. The smaller one is sufficient for the majority of cases, but the fenestra is not capacious enough to admit the bases of the extraordinary glands we occasionally see. It is advisable to remove the whole tonsil, and as the tops only of the largest tonsils can be severed with the smaller instruments, it may be better to have the larger size if but one size is to be kept.

The blade is so protected as to make it impossible to wound the ascending pharyngeal, or the internal carotid artery. The shaft that propels the blade is of such width as to make the use of a gag unnecessary, for it protects the finger of the operator from the patient's teeth, if it is placed in the mouth to ascertain when the fenestra is in such position as to embrace the whole tonsil, as it is necessary for one to do when operating in children with other tonsilotomes. Since I have used this guillotine I have not had my finger bitten, while it was not an uncommon occurrence before to come off second best, as far as pain was concerned. With the shank wide enough to afford protection it is unnecessary to introduce the finger into the mouth, for the teeth and lips cannot close enough to prevent the operator from seeing plainly the field of operation. There is no working in the dark, or fear of damaging structures you do not wish to attack.

The handle is firmly fixed to the shank with a hinge-joint and self-acting spring-lock, so that the fenestra can be pressed down around the base of the gland with any degree of power desired. This feature dispenses with any necessity for hooks, forceps, needles, or barbs for spearing the tonsil. The latter being a soft, fleshy mass, adapts itself

to the shape of the fenestra and protrudes through it the instant its base is pressed about. The pair of spearing or tearing the tonsil by toothed or barbed accessories, designed to drag the gland through the fenestra before the blade cuts, excites the most vigorous struggling and resistance on the part of a child. Even when the utmost care has been exercised, the barbs have pierced the soft palate, or the surgeon's finger, instead of the tonsil. Moreover, the gland always comes out with the instrument, the same as though barbs were used. There is another important advantage in having the handle attached to the shank with a hinge provided with an automatic lock, for the cutting extremity of the instrument cannot be thrown out of your control by a disturbance of the coaptation of its parts. The last time I operated with a Mackenzie tonsilotome the child jumped just as I was placing the fenestra about the tonsil. The shank revolved upon the handle, leaving the latter in my hand, while the cutting end was entirely displaced and removed from the vicinity of the gland. It is impossible for this improved tonsilotome to play you such a trick. The handle is made of rubber, knurled so as to afford a firm grip, and it contains a concealed spring-lock operated by a convenient thumb-plate. When this is moved downward the hinge-joint is unlocked, and the instrument folds upon itself like a pocket-knife, occupying the space of about an inch and a quarter in width and thickness by six and one-half inches in length.

Another pertinent point that should not be neglected in this age of antiseptics, is the provision for cleansing and disinfecting the three pieces of which the instrument consists. By raising the proximate end of the horizontal top-spring of the shaft and swinging it 90° to either side, it becomes disengaged from its lock and it liberates the blade from the shank. This arrangement makes it as simple as possible for taking apart, cleansing and putting together again.

In amputating the apex of a relaxed and elongated uvula the tonsilotome should be used with the handle directed upwards. It should occupy just the reverse position as a uvulotome to the one it occupies when used as a tongue depressor.

Another merit that is not too small to mention is that its simplicity of construction renders it inexpensive.

A NASAL SPECULUM.

The nasal speculum that I have constructed will require but a moment to describe. It is made of spring wire, is self-retaining, and as simple as such a thing can be made. The surfaces that come in contact with the mucous membrane are flattened so as to relieve the pressure of its accompanying discomfort as far as possible. The amount of pressure exerted by expansion can be accurately modified by the counter thumb-screws.

When the speculum is in position, entirely within the vestibule, for examination or operation the handle is directed at such an angle as to be out of the way of the operator. The tendency to slip out of place is overcome by its lightness, and by a nice adjustment of its set-nuts.

A nasal speculum is a disagreeable tool at best, on account of the sensitiveness of the nasal cavities, but this one carries as little discomfort with it as any effective speculum can.

These instruments are manufactured for me by Charles Truax & Co., of Chicago.
719 West Adams Street.

OOPHORECTOMY FOR PROLAPSE OF RIGHT OVARY INTO DOUGLAS' CUL-DE-SAC.

Read before the Medical Society of the District of Columbia, April 18, 1888.

BY J. F. HARTIGAN, M.D.,
OF WASHINGTON, D. C.

This was a very unpromising case. The patient, æt. 36, unmarried, has been under my treatment almost constantly for the past nine years. When she was only a month old her mother died of phthisis. Being a puny, delicate, bottle-fed infant, she was raised with great difficulty. In early childhood she was a subject of chorea.

I was first called to see her in January, 1879, for pleuritis and pneumonia. In the summer of the same year she had intermittent and typhoid fever, the anemia following leading to ascites and dropsy of pericardium. On account of several attacks of hæmoptysis she went to England in November, 1879, on a visit to relatives, and stayed fifteen months. The trip was partly beneficial, although while away she had three hæmorrhages. Several lighter ones occurred after her return, but with the exception of the occasional coloring of the sputum, none have occurred for five or six years. These hæmorrhages were not vicarious, as they came on without regard to the periods of menstruation; besides, the other symptoms, as

cough, expectoration, etc., pointed to manifest lung disease. About the year 1884 nasal catarrh appeared, associated with endometritis and hyperplasia of the cervix, which would yield to treatment for a while, but return from time to time. Another circumstance in the case, which may be well to mention, occurred last October. After a heavy dinner she said she would have to sit down, complained of a swimming of the head, everything appearing dark before her, and immediately lost her senses and slid off the chair. The servant in her alarm dragged her to bed by the shoulder, dislocating it. This was easily reduced upon the administration of ether, although several weeks elapsed before she had the full use of her arm.

Her first pain in right inguinal region dates back to October, 1886, when, as she states, while riding in a street car she was severely jolted by the car running off the track; pain followed immediately, which subsided the same night, recurring when she walked or rode.

In May last she suffered a severe exacerbation while in Virginia. On my return from abroad last October I found her practically bedridden, with marked evidence of phthisis. Under the use of cod-liver oil and other building-up treatment she improved to a remarkable extent, but still complained of a dull sickening pain in right inguinal region. This was aggravated by any attempt to walk across the room, upon defecation, and before, during or after menstruation. I now for the first time discovered retroversion of the uterus, and on digital examination, prolapse of the right ovary into Douglas' cul-de-sac. How long the latter condition existed I am unable to say, but probably its starting point was in October, 1886, as already mentioned; the symptoms in the interim being mitigated principally by rest in the recumbent position. It is needless to say that all palliatives, such as bromide of potassium, counter-irritation, hot water injections, and endeavor at reposition by the genupectoral method with lint soaked in glycerine, proved of no avail. Even different kinds of pessaries seemed to aggravate rather than relieve her symptoms, so that hypodermic injections of morphia, and by the stomach, became the rule. These would only give temporary relief, however, the effects wearing off in two or three hours.

At last oöphorectomy was proposed as holding out the last chance of relief from her deplorable condition. To this she and her father readily consented. Accordingly on March 31st I performed the operation at Providence Hospital, assisted by Dr. Joseph Taber Johnson, whose kindness and valuable advice I desire here to acknowledge. There were also present Drs. Bulkley, Crook, H. L. E. Johnson and Osmon, Dr. Cole, the House physician, administering the ether. After the usual incision in the median line, not

much difficulty was experienced in reaching the ovary, and separating it from its adhesions behind the cervix. No oozing of the pedicle followed the removal of the organ with the tube, which, in addition to the prolapse, presented a hæmatoma partially organized, apparently involving one-third of its substance, and commencing cystic degeneration. The patient made a fine recovery, chatting and laughing the next day. Only once the temperature reached 100°. On removing the stitches the seventh day not a particle of pus was seen anywhere; everything was perfectly dry, there being primary union along the whole line of incision. She has had no pain whatever since, has menstruated normally, commencing the third day, and although it lasted five days she would not have been conscious of the fact had not the nurse called her attention to the napkins. Her previous sickness was on March 13th. The night following the operation there was some pain in the line of incision, and nausea, but no morphia or medicine of any kind, except for her bowels, has been administered. It is now eighteen days since the operation. She is sitting up without any pain, although for months previously she was confined to bed on this account. Instead of laying awake at night racked with suffering, she sleeps soundly, relishes her food, and, to use her own language, she intends hereafter to enjoy life. I will keep her in the hospital yet, however, for five or six weeks, hoping that all chances of a return of the old lung difficulty will subside.

The results in this case so far are very flattering, and beyond reasonable expectation. It is also interesting from the fact that the displacement was on the right side, about 25 per cent. only into Douglas' cul-de-sac being found in this situation, the large majority of those reported being on the left side, for well known anatomical reasons.

I may add in closing, the satisfaction that any one of the three conditions presented by the specimen, viz., the prolapse, the hæmatoma, and cystic degeneration, fully justified the operation.

ON THE TREATMENT OF LARYNGEAL AND PULMONARY PHTHISIS BY A SPRAY OF HOT VASELINE IN CONJUNCTION WITH MENTHOL AND IODOFORM.

BY HOWARD SMITH, M.D.,
OF CHARLESTOWN, MASS.

For two years the writer has employed a spray of pure hot vaseline, medicated with menthol, iodoform and ol. eucalyptus, singly or in combination, in the treatment of laryngeal and pulmonary phthisis, with results which warrant him in describing the method with some detail and in

asking a trial of it at the hands of other practitioners.

The employment of fluid cosmoline is best avoided; because it is frequently irritating and somewhat gummy, while the translucent, semi-solid product of the Chesebrough Mfg. Co. is pure, unchangeable and perfectly bland.

In order to conveniently warm and spray this vaseline the atomizer figured above was devised, which being charged, is held over a lamp or other source of heat until the contents are thoroughly liquefied and the nozzle has become as warm as can be conveniently borne by the patient, an essential point which is believed to contribute much towards a successful result.

One nostril is then closed by the nozzle of the instrument, and the rubber bulb is worked vigorously during inspiration, by which the spray is drawn deeply into the lungs, as is evidenced by the sensations of the patient and the reappearance of the spray upon the expired breath.

The nasal passages and bronchial tubes being thus coated, the inspired air must, for some time afterwards, be impregnated with any volatile substance with which the vaseline is medicated, and thus the remedy is carried still further along the respiratory tract.

Rosenberg, of Berlin, has obtained excellent results in the diseases mentioned from endotracheal injections of a solution of menthol in olive oil, but the writer considers a warm spray of mentholated vaseline preferable, particularly because the former requires the attendance of the physician twice daily, while the latter can be administered by the patient himself.

He remarks upon the antiseptic properties of menthol, having found it, in a gaseous form, to be destructive to pure cultivations of the tubercle bacillus, and also states that the well known anæsthetic effect of the drug is cumulative; that is, lasting for a longer period after each injection, and enables the patient with laryngeal phthisis to eat at once without pain. (See article by Beehay in *Braithwaite* for July, 1888.) The strength employed by him is 20 per cent., but 1.5 per cent. has been found enough for use in the atomizer by the patient himself.

Iodoform was several years ago much employed in the treatment of pulmonary phthisis, dissolved in ol. terebinth and sprayed by means of the steam atomizer. The results were encouraging, but the combination was extremely disagreeable to patients and attendants. Cod-liver oil is an excel-

lent solvent for iodoform, and when sprayed floats in the atmosphere of a room in a remarkable way; but, upon the whole, pure vaseline is a better menstruum and, with the addition of a few drops of ol. eucalyptus, the odor is quite bearable and the results sometimes more satisfactory than those obtained from menthol. The formula used is as follows:

R. Iodoformi pulv.	grs. x.
Ol. eucalypti.	gtt v.
"Vaseline".	℥ss.
	mg.

Both menthol and iodoform are antiseptic and anæsthetic, thus fulfilling the two very important indications of allaying cough and modifying expectoration, but in addition have points of difference which will influence the selection of one or the other. Menthol is stimulant to the vascular tissues and promotes absorption, while iodoform possesses valuable alterative properties, hence it is better to select one and keep the other in reserve, as the antiseptic and anæsthetic properties of either are usually sufficient. The addition of cocaine may be necessary in cases of laryngeal phthisis, but one of the other two remedies will usually be found capable of affording, in cases of pulmonary phthisis, great relief from cough, and of diminishing expectoration and improving its character.

Space can hardly be claimed for more elaboration in description of the method of treatment advocated here, and all references to cases may be omitted, as the remedies spoken of have had their respective values determined, the only point which this communication is intended to emphasize being the employment of a spray of hot vaseline as a menstruum.

MEDICAL PROGRESS.

SURGICAL TREATMENT OF SUPPURATING VENEREAL BUBO.—KARL SZADEK thus describes the treatment carried out at the Military Hospital at Kiev:

In beginning bubo, so long as there is no fluctuation, or redness of the skin, simply rest and prevention of irritation or injury to the inguinal region, at the same time appropriate treatment is employed for the soft sore.

If the skin is reddened but fluctuation not well established over the abscess, hot compresses, made with a carbolic solution, are to be applied until there is established complete suppuration of the swelling. Painting with the tincture of iodine does not meet with favor. As soon as fluctuation is made out in the whole abscess and it is ripe, a surgical opening is necessary. A mild degree of chloroform narcosis is recommended, as the necessary steps are very painful. After most careful

cleansing of the skin in the inguinal and genital regions and the thigh, as well with soap, brush and warm water and shaving off the hair of the pubes, the operation field is to be disinfected with a five per cent. carbolic, or a one per cent. sublimate solution. A free opening is then made, in most cases parallel with Poupart's ligament, by means of a small bistoury. The incision must correspond with the length of the bubo. After evacuating the contents any recesses or sinuses are to be separated by means of a pair of scissors and all glands, both those which have suppurated and others which are enlarged, must be removed with the finger, and remnants of glands and firm granulation tissue scraped out with Volkmann's spoon. If an affected gland does not yield, its capsule must be opened with the knife and its contents removed. If the cutaneous covering is destroyed in a large area it is best to cut it away with scissors. It was only necessary in a single case to apply a ligature on account of hæmorrhage. After the bleeding has been stopped with cotton-tampons, the cavity is to be washed out with a corrosive sublimate solution and the whole cavity sprinkled with iodoform alone or mixed with alum, packed with iodoform gauze, and an occlusive dressing applied. The latter consists of a few layers of sublimate gauze and salicylic or sublimate cotton, upon which a mass of jute or tow is placed. The whole is then covered with mackintosh or glazed paper and fixed with turns of a moist, wide dressing bandage.

The first permanent dressing, when well applied and the patient keeps quiet, can remain for from two to five days. If it becomes soaked with the secretions it may have to be changed earlier. In the second dressing the edges of the wound are washed with a five per cent. carbolic or a one per cent. sublimate solution, the wound covered again with iodoform without washing out the cavity or applying tampons, and a fresh dressing applied. This and following dressings can, with few exceptions, be left from five to ten days and changed only if oozing is noticed from the edges. Besides the 274 chancreoidal buboes there were treated during five years twenty-six syphilitic buboes, and twelve times the inguinal glands were removed by operation on account of tubercular adenitis. The duration of treatment of chancreoidal buboes averaged thirty days. Complications with phlegmon diphtheria. Chancreoidal destruction of the walls and edges, etc., were never encountered in the acute or subacute chancreoidal buboes. In five cases erysipelas occurred, but it seemed to have little influence on the course of the result as healing always took place. In twelve cases eczema of the neighboring parts came on, delaying healing from ten to twenty days, as the dressing had to be frequently changed. The course of the opened suppurating syphilitic buboes, which were usually not scraped out but had

the glands respected, was usually favorable and no complications occurred. In tuberculous adenitis the wounds healed kindly and for the most part quickly when the individual was strong and otherwise healthy, after extensive scraping out and extirpation of the glands. In anæmic and broken down patients, the healing was slower. Although iodoform was employed in large quantities, intoxication from it was never witnessed. In all the varieties the scar was as a rule smooth, even often linear, and after a time scarcely noticeable.—*Journal of Cutaneous and Genito-Urinary Diseases*, September, 1888.

CARDIAC HYPERTROPHY WITH VARIABLE MURMURS; PROBABLE OCCLUSION OF THE THORACIC AORTA.—The following case came under the care of SIR HUGH BEEVOR and DR. DUFFIN, at King's College Hospital, London:

W. B., æt. 24, was admitted into the hospital complaining of pain in the right side, with a temperature of 100°. These symptoms left him after a few days. He was a soldier. He had previously had very good health but, after two years' service, was discharged invalided. Through the kindness of the medical department at the Horse Guards, his health-sheet was obtained, where he is described, on enlistment, as a laborer with good physical development. He was sent to India, where he was in hospital on four occasions for diarrhoea and dysentery, spending 120 days out of 15 months in hospital; he was then sent home to Netley and, after 14 weeks, discharged for heart disease. Habits intemperate. His brothers and sisters are alive and healthy; the father and mother died of tumor. The chest showed a fulness below the right axilla, and strong pulsation could be felt there, and be traced up into the axilla; on the back large arteries could be traced on either side, from the level of the first dorsal vertebrae down to the sixth and fifth on right and left side; and corresponding to the pulsation in the right axilla, a pulsation was felt in the left; the arteries ran down to the ninth and eighth intercostal spaces respectively. The right subclavian was larger than the left; an artery was felt under the right costal cartilages, near the sternum. In the abdomen, the abdominal aorta could not be felt pulsating, only the right external iliac; in the lower limbs the femoral arteries could not be felt pulsating, only the right posterior tibial artery. The pulse at the wrist was 100, high tension, and the artery large; there was also marked pulsation to be felt behind the manubrium sterni. There was visible præcordial pulsation in the fourth and fifth interspaces, but the apex beat was felt most in the sixth, at the nipple line; præcordial dulness was increased. On auscultation, three distinct areas of systolic murmur were noted; at the base, to the right of the sternum, in the second and third interspaces, and to the left in the second and all

the first interspace; below, a systolic murmur was heard over the area of cardiac dulness, and across the sternum to the right costal cartilages. The character of the murmur was different at base and below; at the base, on the right, it was very whizzing in character, and in time came just before the second sound; below, on the left, it resembled an exocardial murmur; on the right it was louder, and of a different character. He was examined at different times over a period of nine months; on some occasions there was no murmur at all at the base, and a limitation of the usual area was frequent, which was shown on the chest by the double contour of the areas marked.

In this case it seemed that the posterior scapular, the subscapular, and the internal mammary arteries had taken the chief part in forming anastomoses between the arch of the aorta and the aorta in the thorax, with the effect of almost obliterating all pulse in the arteries of the lower extremities. No other effect was noted, with, perhaps, the exception of signs of high blood pressure in the renal arteries, the urine being pale and of low specific gravity, with no albumen, and he said it was customary with him to rise once or twice at night to pass water. There seemed to be no evidence, on auscultation, by which the murmurs could be assigned to arterial anastomoses solely, though one area extended down over the cartilages, beneath which an artery could be felt; on the other hand, he said he had been laid up since leaving the army, a week at a time, with severe præcordial pain, and in the fifth interspace the murmur was similar to exocardial murmurs.

This anomalous case could readily escape observation in an ordinary examination; for unless the stethoscope was placed over one of the arteries in the back, there was nothing but the fulness inside the right axilla to cause special attention. Though his heart was carefully examined for some days after admission, it was the fulness and slightly diminished resonance being investigated that called attention to the anastomoses.—*Brit. Med. Jour.*, August 4, 1888.

TREATMENT OF FRACTURE OF THE PATELLA BY SUTURE.—DR. A. R. JENKINS, of Henderson, Ky., proposes to put the skin on the greatest stretch and to cut down on the fragments by a transverse incision—whether the skin be drawn up or down depending on the amount of separation of the upper fragment. Naturally the incision would be made above if there was much retraction; or if there be much contusion of tissue on or below the bone, the incision is made above in the sound tissue. Through either of these openings the fragments could be freed alternately, and inspected, then sawn, drilled or sutured as might be; or an hæmarthron or fluids could here be removed from the joint, the capsular ligament sewn, etc. An assistant, in the meantime, keeps

the skin stretched as necessary, either with fingers, retractors, or Muzeaux forceps. Of course the strictest antiseptic prophylaxis and treatment should attend throughout.

In cases of compound fracture of the patella, with much destruction or pulping of the skin, it is suggested that the doubtful tissue be excised, and that the sound skin be drawn over the fragments. Compensation for the resected skin could be obtained by incising a large Y or an arc above or below the resection wound and far enough removed to be safe, the concavity of the arc or the fork of the Y looking towards the wound, or by a tenotomy of the tensor vaginæ femoris muscle.

Furthermore, it can be said for this method that it would allow of the extra-articular methods of suture, as employed by Volkmann and Riedel, or the intra-articular fastening of Kocher. Either of these methods could be used after the toilet of the patella was complete; all that is then necessary after the skin is relaxed, and the parts *in statu quo ante*, is to make a counter opening at the opposite end of the patella, and from these two openings the catgut or silver could be manipulated by an armed needle around or beneath the patella (subcutaneous or subpatellar). In laying the last stitches in closing the cutaneous wound as a refinement of technique, wounding of the skin could be avoided by the continuous sunken catgut stitch, thus eliminating infection through the skin appendages.

The particular claims for the method are that it admits of an almost subcutaneous exploration and operation on the diastasis and in the joint, and that it may even progress like the ideal subcutaneous wound to healing. It involves normal and less suspicious tissues. It is consistent to true plastic surgery, and to the anatomy and physiology of the parts involved. By making a proper use of the elasticity of the skin in this situation, the wound in most cases need be but small for the field of inspection and operation, owing to elasticity of the skin, can be moved from one part to another without the necessity of essentially enlarging the original cut. In this it resembles the laparotomy technique of Lawson Tait, in so far that it is an endeavor to bring the entrance operation wound to the *minimum*.—*Annals of Surg.*, September, 1888.

MERCURIC BICHLORIDE IN HYPOPYON KERATITIS AND OTHER CORNEAL DISEASES.—DR. R. H. CHILTON says:

In the application of this remedy to eyes with hypopyon, I do not think it necessary to keep the eyes in constant contact with a solution of it, but think a thorough application to the eyeball, by inversion of the lid, two or three times a day by the physician, then direct the patient to use it every three hours, is sufficient. The result is generally about the same—that is, to check

sloughing and suppuration within twenty-four hours. I agree with Dr. Hotz in believing the resulting cicatrix in these cases to be much less than when treated by other remedies. In all cases where sloughing has occurred to the extent of perforation, or where it is necessary to make a paracentesis, I think it is advisable to wash out the anterior chamber with a weak solution, the strength to be about 1 to 20,000. This will prevent a further invasion of the disease into the chamber, and often prevent disease of the iris from complicating the already serious trouble. Any ulcerated surface, without secretion of recent occurrence, will soon heal, and we obtain this condition perfectly by the use of mercuric bichloride.

In the treatment of a recent case of gonorrhœal ophthalmia, I was pleased, not only with its action in at once arresting the progress of a sloughing ulcer in one eye, but in aborting the disease in the other. In the latter, the treatment was begun before the disease had involved the whole of the surface of the conjunctiva, yet suppuration was abundant from the lower palpebral membrane. The disease succumbed in three or four days. In the sloughing eye the disease never progressed after the first twelve hours, and the suppuration was materially checked from the lids at the same time.

The use of this preparation is well borne in hypopyon keratitis; I have thought better than in eyes without ulceration. It is applicable in nearly all cases, while preparations of mercury in the form of an ointment are totally inadmissible from their irritating effect. I have never had occasion to make a paracentesis when I could get the eye fully under the influence of this drug before the accumulation of pus took place. In its application I use a $\frac{1}{2}$ per cent. solution of cocaine to modify its stimulating action. In other forms of corneal ulcer I have found it superior to other preparations of mercury. In ulcerative keratitis, phlyctenular disease, and corneal ulcer from granular inflammation, I have found it equally as beneficial as in hypopyon.—*Texas Courier-Record of Medicine*, August, 1888.

SALICYLATE OF BISMUTH, combining the astringent properties of bismuth and the disinfecting properties of salicylic acid, has been used by EHRLING in a large number of cases of digestive disturbance in children. It is an excellent remedy for gastro-intestinal catarrhs depending on abnormal fermentation, especially if it be administered in conjunction with lavage (washing out of the stomach and intestines). Ehrling uses the following formula:

Salicylate of bismuth	5 j
Glycerine	3 ss
Water, ad.	5iv ʒ

S.—A drachm, more or less according to age, every two hours.—*Archiv für Kinderheilkunde*, Bd. ix, S. 90.

SATURDAY, SEPTEMBER 22, 1888.

CLASSIFICATION OF DISEASES BY COMPARATIVE NOSOLOGY.

It was in every way appropriate that the admirable address of Dr. Gairdner before the British Medical Association should have been followed by the Address in Medicine of DR. T. CLIFFORD ALLBUTT, on "The Classification of Diseases by Means of Comparative Nosology." Reading this after the address of Dr. Gairdner, one is inclined to think at times that Dr. Allbutt's address is a first chapter after Dr. Gairdner's masterly introduction—a rather special application of the general principles laid down in the President's Address. It was such an address as could be written only by a physician-naturalist—a *Naturforscher*. The keystone may be said to be evolution—as applied to disease, and one who reads it will do well to read Mr. Pittfield Mitchell's recent work on "Dissolution and Evolution and the Science of Medicine."

What is meant by "the classification of diseases by means of comparative nosology?" To classify things is to think of them in groups, these groups being in such order as best conduces to the ascertainment and remembrance of their laws. Scientific classification, then, must be founded on a natural method and on natural affinities, and must be the expression of them. We are all familiar with chemical classification, the groups and series, which may be regarded as the simplest classification of substances apparently unlike in

some or many particulars. Passing to the animal world, who, in making an artificial and unscientific classification, would place the kangaroo and the opossum in the same class, and who, in the same classification, would not class together the flying-squirrel and the flying-squirrel-like marsupial of New South Wales? "A scientific classification," said Dr. Allbutt more than twenty years ago, "disregards the obvious as such, and may place together objects at first sight distant and disparate." We should not think of diseases as isolated disturbances, but that many of them are phases of certain periods of bodily development.

In his article on the "Classification of Disease," in the second volume of Guy's Hospital Reports, Dr. Allbutt said: Life consists of a series of processes which together constitute varieties or modes of growth, that is, health, scrofula, syphilis, rheumatism, gout, rickets, tuberculosis, etc. Diseases, taken severally, are often members of such series, which series may be constructed by a survey, not only of the individual, but of his collateral kin and of his ancestry, and also of other orders of the animal and vegetable world, a survey which cannot be made until comparative nosology becomes a recognized branch of our science." And again, in an address in 1882, Dr. Allbutt said: "To find new arms against disease, we must have a truer conception than we mostly have of the genesis of disease. No mere enumeration of symptoms or of pathological detail will suffice for this, nor even a full description of diseases severally. We have to work out the genetic affinities of diseases, their origins, parent stems, and alliances, as well as their issues. We can have no complete therapeutics until the science of comparative nosology is in a great measure constructed—a science as yet scarcely begun." Thus we see that the address now under discussion is the outgrowth of almost a quarter of a century of thought. In this time something has been done in the ways he indicates. About a quarter of a century ago, in 1864, Dr. Laycock showed that some basis of organic classification of disease was to be sought in a comparison of diseases as they originate in the several layers of the embryo, and his suggestion has thrown a great deal of light upon the kinship and genesis of neoplasms. Veterinary science has given and will give new light, but it will advance us only a step. In human nosology but little remains, and when we shall

have all that veterinary nosology can give we will have but two links in the zoocentric or biocentric chain. Perhaps to complete it we must wait patiently for some Darwin, "a machine for grinding general laws out of large collections of facts."

"Perhaps," says Dr. Laycock, "no morbid change happens to man which is not a normal process in other organisms, and the nature of which may be known by a study of such analogous normal changes." An example of this, says Dr. Allbutt, is the shedding antler of the deer, which is a huge sequestrum, a case of normal necrosis. We are in the position, he says, of anatomists before the time of Cuvier and von Baer. A minute clinical study of human nosology has been made, but the parts into which disease has been dissected are not the elements out of which it has grown. Nearly all remains to be done in tracing the homologies of disease throughout the animal and vegetable world. Its phenomena must be studied under the various and simpler conditions of lower organisms, and its development traced upwards through the macrocosm of all life and through the microcosm of the embryo. Its variations through space and under changed climatic conditions must be studied, and the effects of change of function upon change of structure must be noted as these changes pass, by hereditary transmission, from the dynamic to the static form, tabulating pathological sequences in family, race or country, so as to detect the latent affinities of diseases apparently not related. As an introductory to this study may be recommended Quatrefages' work on "The Human Species."

Dr. Allbutt then describes the four methods, the *hereditary*, the *historical*, the *geographical* and the *experimental*, that must be pursued in order to attain to a true system of classification of diseases of men, animals, and plants, on a basis of affinity. These methods must be pursued at the same time; they cannot be logically dissociated. We are, as it were, scarcely at the threshold of any one of these methods, as Clodd says of the significance of the doctrine of heredity. How little does any one of us know of his family history, even in the male line, for a comparatively short time, and how infinitely small the knowledge of the vast expansion backwards of the family tree. Yet for complete knowledge the hereditary nosology of a whole nation is inadequate; we must go

with our inquiries into the diseases of all living things. As in all studies, the historical method in nosology leads to the philosophical, and here we may be said to be in the glacial period of our knowledge. How do changes of function become, in generations, changes of structure, variations into less useful or "morbid" function, and this soonest in the highest and least organized parts, the nervous system, the adapter and organizer? We know only the fact, not the *how* and *why*.

And after having carefully studied, so far as we can, the heredity and history of disease, and turn to the geographical method for information, we are brought face to face with the question, How have the morbid varieties of *man* arisen? For the answer to this, which is only a part of the question, How have the morbid varieties of living things arisen? we must seek the answer in the past. We must work in areas long undisturbed, says Dr. Allbutt, and must register in these the phenomena of morbid variation with the qualities of soil, aspect, seasons, atmosphere, food products, and so forth. Nations must not be confounded with races, nor kingdoms with physiological areas. Said Boudin: "As every country has its characteristic vegetable kingdom and animal kingdom, so it has its pathological kingdom." As illustrating the fact that no one of the methods of classification spoken of can be relied upon for complete nosological data, may be mentioned malformations of the jaws, which are becoming more common in America, especially in those portions of the continent peopled by several different races. And to show the value of comparative nosology, in clearing up this one matter we must get a part of the answer from the *niata* cattle of South America; a part from certain sheep of Central Asia, which have, normally, steatopygia; a part from the difference between the head of the domestic pig and the wild boar, and so on until the whole world has been sought over; and even then human craniology must be studied to complete the evidence.

Finally, with the other methods, there is the experimental. Like the other methods, the experimental shows that clinical types cannot be a basis of nosological classification. The work being done in experimental medicine is increasing, and is certainly productive of interesting results. Pharmacological experiment has shown that poisons vary in their clinical effects by leaps and bounds,

as musical flames respond to scales of vibration; that poisoning by extractives in general is attended by hyperthermia, and poisoning by animal alkaloids by hypothermia; that the distinctive action of the lower members of the fatty series is their stimulant and anæsthetic action on the nerve centres, and that the members of the aromatic series affect the nervous system, but the motor more than the sensory centres. With curare we may reduce the mammal to a cold-blooded animal, whose temperature varies with the atmosphere. Space does not permit the further pursuance of this subject.

HOW THE OPIUM HABIT IS ACQUIRED.

MR. VIRGIL G. EATON tells the public, in the September number of the *Popular Science Monthly*, how the opium habit is acquired. He is the writer that frightened the people of the country about two years ago by prophesying that they would all be bald in about a dozen centuries. He now predicts that unless people develop their muscles, rest their nerves, and send the family doctor on a vacation, the residents of our American cities will be all opium-slaves.

For the past year or more Mr. Eaton has "studied the growth of the opium-habit in Boston." He says it is increasing rapidly, and from the "tell-tale pallor" of the faces he sees he is sure the habit is claiming more slaves every day. In order to approximate to the amount of opium in its various forms used in Boston, Mr. Eaton "made a thorough scrutiny of the physicians' recipes left at the drug-stores to be filled." This is the way that one would expect an unscientific and unthinking man to make such an investigation. Having set out to find a thing, he finds it—and is duly surprised. He says he found opium and its alkaloids used by physicians for every ailment that the flesh is heir to, and then he enumerates a list of affections for which he learned they are used. It is pertinent to inquire whether Boston physicians are in the habit of writing out a diagnosis on each prescription. One would infer as much from Mr. Eaton's article. From his investigations as to the number of prescriptions containing morphine, and the number of these refilled, he is satisfied that it was the opiate qualities of the medicine that caused the renewal. As regards the proportion of

opium habitués that begin by taking medicines containing opiates, he places it as fully 25 per cent.—perhaps more. This is only one in four, on his own estimate. Then, within the space of a page he says: "The parties who are responsible for the increase of the habit are the physicians who give the prescriptions." Now if only one opium habitué in four acquired his habit from medicines ordered by a physician, the other three must have acquired it in some other way, not attributable to the act of a physician. How, then, can the physician be responsible for the increase of the habit, even admitting that they are responsible for one case in four?

Mr. Eaton also tells how physicians prescribe opium. "In these days of great mental strain, when men take their business home with them and think of it from waking to sleeping, the nerves are the first to feel the effects of over-work. Opium effects immediate relief, and the doctors, knowing this, and wishing to stand well with their patients, prescribe it more and more. Their design is to effect a cure." This arrant nonsense in the *Popular Science Monthly*! Mr. Eaton says that two means of preventing the spread of the habit suggest themselves to every thoughtful person: The *first* is to pass a law that no prescription containing opium or its preparations can be filled more than once without having the physician renew it. If this and the registration safeguards were not enough, Mr. Eaton suggests that physicians could be fined for administering opiates save in exceptional cases. The *second*, is to keep the body in such a state that it will not require sedatives or stimulants. People, he says, should forsake medicine and take to the gymnasium, and thus the family doctor, who means well, but cannot resist the tendencies of the age, can take a protracted vacation. All of which is doubtless well meant.

Had Mr. Eaton taken the trouble or known how to make more careful investigation of the subject about which he has succeeded in confusing himself, he would have consulted some of the back numbers of the *Boston Journal of Health*, with the assistance of which he might have written an article at once sensible and interesting. Had he stopped to consider that one-fourth of a class is less than three-fourths, he would not have written an article that can have no other effect than to mislead the public. He but barely men-

tions the fact that the proprietary or "patent" medicines that have the largest sales are "those containing opiates." He also mentions that opium joints and opium-smoking are on the increase. He says nothing of the fact that "nervines," and such compounds as "Scotch Oats Essence" contain opium, and probably he does not know that of the twenty or more varieties of "opium cures" made and for sale in this country, *all contain opium* except one, as shown by the analyses of Dr. B. F. Davenport, of Mr. Eaton's own City—Boston. Mr. Eaton takes no account of the fact that the "patent" medicines of the worst grade are the most popular, and their popularity depends on the amount of alcohol or morphine they contain.

Mr. Eaton's paper reminds one of the assertion that a large proportion of habitual and occasional inebriates owe their disease to the alcohol that physicians have prescribed. This assertion has been recently made by a prominent clergyman, whose name may be found among the endorsers of a "patent" compound that contains more alcohol than pure sherry. He thunders from the pulpits against the use of alcoholic liquors in any and every form, and writes an endorsement for a "pure, non-alcoholic tonic" that contains 29 per cent. of alcohol. Totally blinded by the beam in his own eye, he lectures his brethren on the motes in their eyes. The medical profession, we have no doubt, will endorse Mr. Eaton's proposition to fine physicians for prescribing opium when it is not needed, if he will accept an amendment: Fine druggists and others that sell "patent" medicines containing opium or its preparations or alcohol, or any substance dangerous to health or of no value in the treatment of disease, or that are not worth their price; and incarcerate the manufacturers in State's prison for not less than five years, along with the people that endorse their preparations, knowing nothing of them. This done, Mr. Eaton will probably find that physicians are not responsible for the increase of the opium-habit.

INTUBATION AND DEGLUTITION.

It is well known to all who have given attention to the subject, that one of the greatest difficulties attending intubation of the larynx as a substitute for tracheotomy, is the tendency of food

and drink to enter the larynx through the tube, rendering it, in some cases, impracticable to administer sufficient nourishment to sustain the patient. At the regular meeting of the Chicago Medical Society, September 3, 1888, Professor Wm. E. Casselberry read a short paper embracing an account of three cases of intubation of the larynx that had come under his observation, in which he had succeeded in administering water, milk, and other liquid nourishment abundantly, by simply placing the patient in the dorsal position, with the head and shoulders inclined downwards at least sixty degrees, and letting them take the liquid through a tube. While inclined in that position, the patients swallowed with ease and without the slightest tendency to pass any part of the liquid into the larynx. His first case was attended with Dr. Frank Carey about June 1, 1888. Since hearing of the good results obtained in this case, several other members of the Society had tried the same method with equal success. In none of the cases thus far reported, has the great inclination of the head and shoulders downward, created any tendency to displace the tube, or to cause undue congestion of the vessels of the brain. Professor Casselberry stated, in closing the discussion, that the patient should not be raised to a horizontal or upright position too quick after stopping the food or drink lest there might be remaining in the mouth or fauces enough to gravitate through the tube in the larynx and occasion coughing at once. He said to obviate this it was necessary to induce the patient to perform the act of deglutition two or three times after taking away the nourishment or drink and before allowing the head to be elevated.

YELLOW FEVER IN FLORIDA.

The yellow fever that manifested itself to a limited extent in two or three places in Florida last year, has renewed its invasion the present season, and assumed an important epidemic form in Jacksonville and some smaller places. The whole number of cases reported as having occurred in Jacksonville to this date, September 17, is 1047, and the number of deaths, 133, which indicates a mild type of the disease. Liberal contributions are being made in aid of the suffering communities; and this should be continued, especially by the people of the North, until the

plague ceases. If the Health Boards and afflicted municipalities are supplied with sufficient means, not only provisions, but plenty of nurses and doctors can be had from the South, who are already acclimated and familiar with the scourge. But experience has abundantly demonstrated that such nurses and doctors as go from the North wholly unacclimated, directly into the fever locality, almost certainly speedily succumb to the disease, and thereby become an additional burden instead of a help to the afflicted communities.

EDITORIAL NOTES.

A CONGRESS of Polish medical men and scientists was held recently at Lemberg. About 500 members were present.

ALUM IN FURUNCLES OF THE EAR.—Grash reports good results from alum solutions in furuncles in and about the ear.

RAILWAY SANITARY INSPECTION.—Those interested in this field will do well to read the paper of DR. R. HARVEY REED, of Mansfield, Ohio, on "The Sanitary Inspection of Passenger Coaches," read at the Ninth International Congress, and now reprinted in a brochure.

LEAD-POISONING has become less frequent in the Department of the Seine, the hygienic measures enforced for several years having diminished the number of cases. The Committee on Public Hygiene recommend that powdered white lead be replaced by white lead mixed with oil, which is not dangerous.

ABSENCE OF BOTH MAMMÆ in a female, aged 21 years, is recorded by DR. W. WYLIE, of Skipton, England. A small mole exists near where the right nipple should be found, and the pectoral muscle seems to be quite bare of adipose tissue in that region. Some three months ago the woman gave birth to a child, and there has been no sympathetic pain nor uneasiness of any kind in the pectoral region.

MEASURES AGAINST SMALLPOX.—The Comité Consultatif d'Hygiène Publique de France, after hearing the report of Dr. Roux in regard to the epidemic in the Department of Morbihan, made the following recommendations: Isolation of patients; disinfection of linen, mattresses, and

clothes by means of portable steam stoves; the use of sulphuric acid and antiseptic sprays in the dwellings; vaccination of all the inhabitants with animal vaccine; and special instruction promulgated by means of cards.

SPECIALISM IN FRANCE.—The Council of the Faculty of Medicine of Paris has approved the report of Dr. Damaschino, who urges that three *agrégés* (assistant professors) out of five should be required to take up specialties immediately on their *agrégation*, and thus official sanction has been given to specialties, in France at least. The specialties to be chosen comprise ophthalmology, experimental and comparative pathology, hygiene, forensic medicine, mental diseases, and cutaneous diseases and syphilitic disorders. Therapeutics, nervous diseases, and diseases of children will be added to the list subsequently.

SUIT AGAINST DR. VANDERPOELE.—Dr. Samuel C. Vanderpoele, Jr., of New York, has a singular lawsuit against him. Three weeks ago he diagnosed the illness of a little daughter of Charles Dawson, of Syracuse, N. Y., who was spending some time with his family at the Larkins House, Watch Hill, L. I., as scarlet fever. Mr. Larkins, the proprietor, relying on the diagnosis of another physician, denied that the child was suffering from the disease, and the Dawson family remained at the hotel. The other guests, hearing of Dr. Vanderpoele's diagnosis, left the place. Mr. Larkins immediately brought suit in Rhode Island against Dr. Vanderpoele for \$12,000 damages. Dr. Vanderpoele says that his diagnosis was correct and that he has been sustained by the Board of Health of Westerly, R. I., and some prominent physicians. Dr. Vanderpoele intends fighting the suit. He says he was subjected to great personal inconvenience by the action of Mr. Larkins, who, as soon as he brought the suit, had an order issued for Dr. Vanderpoele's arrest. The Sheriff arrived at the Watch Hill House, a rival establishment, where the physician was staying, and proceeded to execute the order. Bail was fixed at a large figure, but several of the cottagers offered at once to go on the doctor's bond. The Sheriff, however, Dr. Vanderpoele says, made paltry objections to each of them, and stated that he intended to lock the doctor up, but satisfactory bail was finally furnished. Dr. Vanderpoele says he will in turn sue the hotel man for damages.

SOCIETY PROCEEDINGS.

Congress of American Physicians and Surgeons.

THE PRESIDENT'S ADDRESS.

Delivered at Washington, D. C., September 20, 1888.

ON MEDICAL MUSEUMS, WITH SPECIAL REFERENCE TO THE ARMY MEDICAL MUSEUM AT WASHINGTON.

BY JOHN S. BILLINGS, M.D.,
SURGEON, U. S. A.

Through the kindness of Dr. J. S. Billings, we have received an advanced copy of his Address. After some introductory paragraphs he speaks of the origin of Museums as follows :

The origin of collections of objects of natural history was possibly, as suggested by Beckman, the custom of keeping curious objects in temples; but we have no record of the formation of any collections, specially connected with anatomy or medicine before the sixteenth century. It is true that the human anatomy had been introduced into the schools by Mundinus in 1306, and that do doubt in Bologna, in Paris, and a few other places, a skeleton or two was preserved for purposes of instruction; but alcohol was unknown as a preservative before the end of the fifteenth century, anatomical details were of no interest until Vesalius had stirred up controversy with the Galenists, and injected preparations were not thought of until after Harvey's announcement, in 1628, of the discovery of the circulation of the blood.¹

The introduction of the use of the microscope at the beginning of the seventeenth century, and the collections of preparations for use with this instrument made by Leeuwenhoek and Ruysch, gave a powerful stimulus to formations of museums of this kind. The most famous of these collections was that of Ruysch, purchased in 1717 by Peter the Great, and sent to St. Petersburg. Ruysch was practically the first to prepare injected anatomical specimens for permanent preservation, and, if the stories told of his work are true, he made preparations which have never been surpassed. His museum was a very ornamental one, the bones and skeletons being arranged in various devices, the plants in bouquets, while scattered through the whole were beautifully engrossed sentences from the Latin poets.

¹ For accounts of the collections formed between the days of King Solomon, and the end of the seventeenth century, consult tome ii of the *Musei Museorum* of Michael Bernhard Valentin, in folio, published at Frankfurt in 1714, wherein are curious engravings of many of the wonders contained in these museums. See, also, Hagen (H. A.), *The history of the origin and development of museums*, American Naturalist, 1876, x, p. 80.

The first use of wax models to represent pathological specimens or dissected preparations of parts of the human body is attributed to a Sicilian priest, Gaetan Jules Zamboni, who lived in the latter part of the seventeenth century, and who had been accustomed to make wax models of diseased or deformed hands, feet,

The most famous medical museum in the latter half of the eighteenth century was that founded by Fontana, at Florence. This still exists, filling a series of rooms, and consists mainly of wax preparations, beautiful to look at, but inaccurate, and of little scientific value.²

During the first half of the present century a number of private collections were formed by anatomists, pathologists and surgeons. Most of these have become public collections, either by gift or purchase, and the rest have been dispersed or destroyed. There is not in existence, at the present time, any large collection of specimens pertaining to human pathology which is the property of an individual, and is at all comparable to those made by John or William Hunter, Astley Cooper, Howship, Liston or others. Commenting on this fact, Sir James Paget writes me that he does not know of any large private pathological collection, and that he believes the change to be entirely for the better.

The necessities of modern progress in anatomy, physiology and pathology, have led to the creation of medical museums in all parts of the civilized world. In most of the Continental capitals, these are connected with universities supported by the State. In Great Britain and in this country they are, as a rule, connected with private or semi-private institutions for medical teaching. This difference is connected with the relative position which medicine holds in the educational machinery of the State in different countries. Where medical education is furnished by institutions directly supported by the government, the museums, which are a part of the apparatus required, are, of course, also supported by the government.

Through the aid of friends, whose kindness in replying, or in obtaining replies, to somewhat troublesome inquiries, I cannot sufficiently acknowledge, I have obtained certain data with regard to some of the most important medical museums now existing in the world, and a part of these data are summarized in the table before you.³ Evidently the city having the most valuable aggregate of anatomical and pathological specimens at the present time, is London, which contains the collections of the Royal College of Surgeons, of St. Thomas', Guy's, St. Bartholomew's, St. George's and of other hospitals, and of University College, the College of Physicians and others. The oldest public anatomical museum in London is probably that of St. Bartholomew's, which, in 1826, had a room set apart for the purpose under

etc. to be used as *ex voto* offerings at the shrines of certain saints. The fame of these induced a Florentine surgeon, Ricci, to visit the priest, and to get him to model some pathological specimens which he furnished. A Franciscan, named Desroches, brought this art to France, and made many such models between the years 1703-1706, and Bianchi formed a large collection of the same kind in Italy. It was scattered after his death, and the last vestiges of it were two models representing a healthy and a diseased liver, which were to be seen in Innsbruck in 1766. (Percy et Laurent, in *Diet. des Sci. Méd.*, Paris, 1818, vol. xxxv, article "Museum.")

³ See appendix.

the charge of John Freke, and which received the private collection of Abernethy. The most important medical museum in the world, and the one which has exercised the greatest influence in giving direction to anatomical and pathological studies, and in serving as a model for the formation of other collections, is undoubtedly that of the Royal College of Surgeons of London, the foundation of which was the collection made by John Hunter, purchased by the government in 1799. In one sense it is not a government institution, the funds from which it is now supported not coming directly from government grants; but, in another sense, it is truly such, since the College may be looked upon as the agent of the government, having special charge of matters connected with medical education, as it is the principal examining body for those proposing to practice surgery in Great Britain.

The great value of the Hunterian collection lies in the breadth of its scope, which includes every branch of medical science; but it is preëminent in illustrations of human morphology and its abnormalities. The museums of the great hospital medical schools are relatively richer in the department of pathological anatomy, specimens of which they have greater facilities for obtaining. Among these there is, of course, a certain amount of duplication of matters of interest; but no two pathological specimens are precisely alike, and the question discussed in the Paris school one hundred and fifty years ago, viz: "*An pro distinctis ægris ægritudines diversæ?*" is one that often occurs to a curator as he examines new specimens which differ but little from those already in his collection, but which do differ in some respects, and with regard to which he must decide as to whether, upon the whole, they are worth the trouble and cost of preservation.

Edinburgh and Dublin have also each large and valuable collections pertaining to anatomy and medicine.* In Paris the medical museums are those of the Faculty of Medicine, including the Musée Dupuytren, devoted to pathological anatomy, and the Musée Orfila, devoted to human and comparative anatomy, *materia medica*, natural history and instruments and apparatus.

Professor Leon Le Fort, to whom I am indebted for data with regard to these collections, remarks that a large proportion of the anatomical specimens of the Orfila museum come from candidates who take part in concours opened for positions connected with the anatomical teaching of the faculty—such as prosectors, demonstrators, etc., each candidate being required to furnish from ten to thirty specimens.

*I am indebted to Sir James Paget for the information given with regard to the greater number of the British museums. I had originally intended to attempt to obtain such data only from four or five of the largest; but on sending my little list of questions to Sir James he took such a kindly interest in the matter as to send a copy of these queries to a number of other museums with the request that they might be answered.

The medical museums of other European countries are connected as a rule with universities, and it is to be remembered that in these the different branches of medical instruction are each both more specialized and more comprehensive than is the rule with us. The professor of anatomy, of physiology, of pathology, has each his own building or institute, and therefore, each his own museum; and unless this fact be held in view, comparisons between Continental and English, or American, medical collections may give very erroneous results.

So far as mere number of specimens is concerned our own national medical collection is one of the eight largest in the world, and is increasing more rapidly than any other.

This collection, known as the Army Medical Museum, owes its inception to Dr. Wm. A. Hammond, one of whose first acts after becoming Surgeon-General, 1862, was to issue a circular stating that "as it is proposed to establish in Washington an Army Medical Museum, medical officers are directed diligently to collect and to forward to the office of the Surgeon-General, all specimens of morbid anatomy, surgical or medical, which may be regarded as valuable; together with projectiles and foreign bodies removed, and such other matters as may prove of interest in the study of military medicine and surgery." By the end of the year over a thousand specimens had been collected, and the catalogue printed in 1866 showed that it contained 7716 specimens. It is not my purpose in this address to trace the history of its development; that must be done elsewhere. It has recently been placed, with the Library, in a conveniently arranged fire-proof building, and on the first of July last contained over 15,000 specimens besides those contained in its microscopical department, divided as follows:

Comparative Anatomy	1,689
Pathological	8,354
Medals	384
Microscopical specimens	10,416
Normal Human Anatomy	2,961
Instruments and Apparatus	814
Microscopes	141
Miscellaneous	835

Besides these there are 375 specimens pertaining to normal human anatomy and 726 to pathological anatomy, which are in what is called the provisional series.

It is not, however, by number of specimens that the importance and value of museums of this kind can be judged; and in this case such a comparison would give an exaggerated and erroneous idea of the value of this collection. My object in this address is not to boast of what we have, but to indicate what we want; to point out what a National Medical Museum, arranged to meet the

5 Circular No. 2, Surgeon-General's Office, Washington, D. C., May 21, 1862.

wants and interests of this country, should be, should have, and should do, and to suggest some of the ways in which this is to be brought about.

After commenting somewhat in detail upon the ways and means for making the museum what it should be the author continues as follows :

One of the most important sections of our museum is that devoted to microscopy, including normal and pathological histology and photomicrographic work. In the cabinets there are nearly 11,000 mounted specimens, illustrating almost every field of microscopical research. Many of these were made twenty years ago and more, and were mounted by processes which have not given good results, so that Dr. Gray, who is in charge of this section, estimates that about 3,000 will be set aside as worthless ; but the rest form a very valuable series to which additions are being constantly made, and materials for which we are specially anxious to obtain. In connection with this section a series of cultures of chromogenic and pathogenic bacteria is kept up for museum exhibits, and also to illustrate methods of work.

While the great majority of the specimens in a medical museum have some relation to diagnosis, prognosis, or therapeutics, the number of those which are of direct interest to the so-called practical physician is not very great. It includes models and casts illustrating dermatology, morbid growths, the results of amputations, excisions, plastic operations, etc., and instruments, apparatus, dressings, etc., of all kinds. Here also may be classed hospital fittings and furniture, means of transportation for sick and wounded, model cases of instruments, emergency chests, etc. Our medical museum has a fair beginning of a collection of this kind, including over a thousand specimens ; but many more are needed to make it reasonably complete. If each medical man who devises a stethoscope, a pessary, a speculum, an ophthalmoscope, or an electro-therapeutic appliance with which he is well pleased, would send a specimen to the collection, its increase would certainly be rapid, and it could always show the latest improvement.

The Army Medical Museum contains what may seem a large amount of material relating to human osteology, and especially craniology, in its relations to North American ethnology, or the history of the development of different varieties of man on this continent ; but it is not actually half large enough to permit of drawing definite scientific conclusions from it. The majority of the crania which it contains have been measured to a certain extent, and the results have been published ; but many other measurements are desirable to permit of comparison with series taken elsewhere, and even measurements already made must be repeated by later and better methods.

We have been trying some experiments with composite photography and superimposed contour tracings as a means of obtaining typical outlines and dimensions for race groups of crania, and these give promise of good results. If the collections of crania of North American Indians in Boston, New York, Philadelphia and Washington could be brought together, a very much better average presentation of the majority of tribes or groups would be obtained than can be furnished by either of these collections taken separately. By composite photography and tracings, combined with uniform methods of measurement, we can practically bring these collections together, and obtain results nearly as satisfactory as if we had them all in one room. We have also fitted up one large room with instruments and apparatus for anthropometry in its widest sense, including psychophysical investigation, and it is intended to make this a complete laboratory for illustration of methods of work.

In London arrangements have been made to have such an anthropometric laboratory in an outbuilding at the South Kensington Museum. The two things have no connection, and it seems to have been placed there because it would obtain more visitors desirous of being measured and tested than if placed anywhere else. In this laboratory, which is, I believe, essentially the same sort of institution as that arranged by Mr. Francis Galton at the Health Exhibition in 1884, and is planned by Mr. Galton, any person can have the regular series of measurements and tests made upon himself for the charge of six cents. There are difficulties in the way of making a charge for such measurements in a government establishment, and there are also difficulties in undertaking to do such work gratis, chiefly on account of the cost. It is, however, so desirable that it should be done, and the data which such observations systematically carried on for a series of years would be so valuable, not only from a scientific point of view, but for practical purposes in connection with life insurance interests, and very possibly with practical medicine, that we should endeavor to overcome these difficulties in some way, and I think it can be done sufficiently, at least, to stimulate private enterprise in this direction. It is possible that we may yet see in large cities establishments of this kind, directed by skilled and reputable physicians having the confidence of the profession, where not only normal but abnormal conditions can be determined ; places where the secretions can be tested chemically and microscopically, ophthalmoscopic and endoscopic examinations of all kinds made, the mode of functioning of muscles and nerves determined, and an authoritative record of the results made for the use of the individual, as evidence of his condition, or for the information of his physician. It would require an already es-

tablished reputation and much skill and tact on the part of the director of such a laboratory, with absolute refusal to give prescriptions or advice in any shape, to make it fully successful; but it may be done.

An important feature of our National Medical Museum should be to show methods of research and of instruction for the benefit of the investigators and the teachers of the country. This includes instruments and apparatus, and, to a limited extent, illustrations of the modes of using them and of the results; it also includes diagrams, models, etc., used for illustrating lectures. For example, as soon as Koch's researches became known in this country, physicians, and especially medical teachers who visited the museum, asked if we could show them the apparatus used by Koch and Pasteur in bacteriological work, and eagerly examined the few specimens of cultures on solid media which we were able to exhibit. The anatomist comes to the museum quite as much to see methods of mounting and preservation, as to see the specimens themselves; the physiologist does not expect to see function directly exhibited, but he does hope to find information about kymographs and constant temperature apparatus, and he wants to see whether Kühne's artificial eye is so useful for teaching purposes that he ought to get one to illustrate his lectures.

The objects of a medical museum are to preserve, to diffuse and to increase knowledge. Its conservative function is to form a permanent record of what has been demonstrated, and to fix the meaning of terms. Even in my brief experience of thirty years the terminology of anatomy, physiology, pathology, chemistry and of most of the specialties has greatly changed, and this not only by addition of new terms, but by the dropping of old ones. To get useful results from the older literature we must know the precise significance of the old words, and, in some cases, the best way to learn this is to examine the specimens prepared by those who used such terms in their descriptions. The specimens in our museum which came from the collections of Professor William Gibson and Dr. Frank Hastings Hamilton are especially valuable, because they were the basis of practical teachings, and should be examined by any one criticising these teachings.

A large proportion of the pathological specimens in this museum illustrate conditions which now rarely occur, forming a group which it is safe to predict will never be duplicated. It is not only that they were gathered during a great war, but that they illustrate the results obtained when antiseptic surgery, as now understood and practiced, was unknown. Never again, I hope will there be brought together such a collection of the effects of pyogenic microorganisms on gunshot

wounds, especially of bone, as may be seen in its cases.

The museum also preserves, for future investigations, objects whose nature or relations are not understood at the time when they are received, and which occur so rarely that the means of studying them by comparison can only be obtained through such preservation.

Upon the function of a museum as a diffuser of knowledge—as a means of education; it is needless to dwell. That it should also strive to increase knowledge is equally certain. This is to be effected by study and comparison of its materials. The results of such study and comparison of a part of the Army Medical Museum collection have appeared in the volumes of the *Medical and Surgical History of the War*. Another part will, I hope, soon be utilized in a study of its collection of human skeletons and crania which has been commenced by Dr. Matthews, of the Army. But a considerable part is as yet only in the stage of agglomeration, and our present business is to collect and preserve, leaving to the future its full utilization.

A medical museum is really used, for purposes of study, by very few persons; but through the teaching of those few its lessons are made known to the whole profession. American physicians in investigating a subject do not, as a rule, think of inquiring as to what museums can show with regard to it, simply because they have not had convenient access to large collections and are not accustomed to make use of them. Thirty years ago we were in much the same situation in respect to medical literature; but as the libraries have grown, desire for bibliographical research has grown also, and I think that in like manner when we have secured a comprehensive National Medical Museum, it will not only be made use of, but will give a powerful stimulus to the formation and progress of other more special collections elsewhere.

What should be the relation of this central National collection to those formed in different parts of the country, either in connection with medical schools, or with museums of broader scope? Certainly they should help one another, and this can be done in many ways. I do not in the least object to a generous rivalry to do the best work, to have the most instructive and artistic preparations. That is a good thing. But I would say to the anatomist of a school, when you have made a preparation which is noteworthy, offer to make a copy for the National collection, where it will be seen by the anatomists of all schools and all countries. To the pathologist of a medical school I would say, after you have secured type specimens for your own collection put aside other good specimens for the National Medical Museum, which will furnish you materials for the purpose.

On the other hand, the collections of the National Museum are available for study by any proper person, and its duplicates should be used to aid other museums which may be in special need of them.

In common with several of the largest and most important medical museums, more especially those of the Royal College of Surgeons and of the Faculty of Medicine of Paris, the Army Medical Museum has the advantage of being closely associated with a large medical library which is in the same building, and at present under the same direction. The increased utility and attractiveness which this gives to both library and museum is very decided.

I have time for only a very condensed statement of the wants of our National Medical Museum. In the first place it needs the intelligent interest and friendship of the medical profession of this country. To a very considerable extent it has had this; were it otherwise it would not be what it is, nor where it is. But it needs more of it, and it can never have too much. Every medical man in this country should help a little and provide for the perpetuation of his name as that of a physician interested in the progress of the profession by sending at least one specimen to it. It is omnivorous in its demands for material, as will be seen by the circular which it has recently issued. But I will name as special wants, human embryos, especially those of a very early age, monstrosities and malformations of all kinds in man or in the lower animals; results of old injuries, such as fractures or dislocations, or of surgical operations, such as excisions, stumps, etc.; injuries and diseases of the eye, ear and nose; new growths of all kinds; diseases of the brain and spinal cord; and specimens illustrating the condition of bones, joints, brain, larynx and other organs in extreme old age.

In the second place it needs a regular supply of funds from the general government. To form and keep in proper condition such a medical museum as this should be is a more difficult and expensive matter than those not acquainted with such work would suppose, and the gifts of specimens from the profession must be supplemented by ample means for the preparation, preservation and proper display of these specimens, and also for the purchase of apparatus and typical specimens of foreign work, in order that the museum may be always able to show the latest state of knowledge and the best ways of doing things.

The annual appropriation for the Museum at present is \$5000. This is sufficient, except that the printing of the catalogue, of which I shall speak presently, must be an extra charge. . . .

The third need of the Museum is a series of the right kind of descriptions of its specimens, given on labels and in a catalogue. Unaided by such

descriptions it has for each man that which he can see in it, and no more. One man will see nothing but an old piece of bone, a shapeless mass of tissue bleached by alcohol, a case of old dingy brass instruments. Another will see in the same things a rare joint atrophy, implying curious abnormal nerve influence; a leprous nodule, whose history, if we knew it, would reach back through the lazarettoes of the middle ages to the far East, and whose bacilli may be the lineal descendants of those that vexed Naaman the Syrian; a case of microscopes illustrating the development of that instrument, from the first rough iron tube of the spectacle-maker of Nuremberg to the delicate and complicated instrument through which we now peer curiously into that world which lies within the world of unassisted vision. By our labors and catalogues we must tell men what to see; but to do this we must first see ourselves. The aphorism that a first-class museum would consist of a series of satisfactory labels with specimens attached, means a good deal. Something has been done in this direction, as you will see on inspection of the cases; but I often wonder what sort of labels a man who has spent years in investigating the normal and abnormal structure and relations of one organ, would write for our specimen of that organ. Such help as this we need; kindly, truthful criticism, the pointing out of errors and of new points of view for this mass of material.

We also need a series of printed catalogues. One of these should be in the form of compact handbooks relating to particular sections of the collection, and intended partly for the use of visitors while in the museum and partly as a ready means of letting distant friends know what material it most needs in different departments. It should also print a complete illustrated catalogue of the whole collection for the use of the investigators and teachers of the profession. Congress has been requested to grant authority for the printing of such a catalogue by the Government Printer. The material for it is nearly ready, and it would make three volumes, each the size of one of the volumes of *The Medical and Surgical History of the War of the Rebellion*.

Our museum, like the library with which it is associated, includes all the specialties. No physician is so learned or skilful that he can find no instruction there, and no one is so ignorant that he cannot comprehend some of the lessons which it teaches. Taken together these institutions should contribute in no small degree to our National prestige, for which eminence in scientific work and teaching is an essential element, and if it be remembered that they are only twenty-five years old, and that during that period we have been making medical history at a tremendous rate, surely some incompleteness and crudeness may well be excused or overlooked.

Speaking in behalf of the Army Medical Department, and for the dead as well as for the living who have been charged with this work, I can truly say that we have been very proud of our charge, and that we have done our best, each according to his capacity and opportunity, to make

the museum and library such as a great profession and a great nation have a right to demand.

Appended to the address are tables enumerating the principal medical museums both in Europe and this country. We have only space for the table giving those in the United States, as follows:

LOCALITY AND NAME OF MUSEUM.	Total number of specimens.	NUMBER OF SPECIMENS IN EACH DEPARTMENT.					Number of specimens added during last five years.	Am't expended during last five years.
		Comparative anatomy.	Normal human anatomy.	Embryology.	Pathological anatomy.	Material medica.		
Albany: Medical College Museum.	5500	250	1250	200	3100	700	770	5660

FOREIGN CORRESPONDENCE.

LETTER FROM LONDON.

(FROM AN OCCASIONAL CORRESPONDENT.)

Dr. William Murrell's Work on Chronic Bronchitis—Medical Advertising in London—Report on the late Emperor Frederick's Case—The next Congress at Washington and Medical Honors—The Father of the American Medical Association.

Dr. William Murrell, of the Westminster Hospital, London, is engaged in the preparation of a work on chronic bronchitis and its treatment, a complaint which is very prevalent here, and to which the Doctor has paid much attention. He is still a firm believer in the efficacy of ipecacuanha spray introduced by him and Prof. Ringer, in 1874. The ordinary ipecacuanha wine is used, either pure or variously diluted, according to the severity of the symptoms. The inhalation is performed once or twice a day and its duration rarely exceeds twenty minutes. The apparatus employed is a common hand-ball spray, or one worked by steam, which is a modification of Siegle's. Certain precautions are taken, which although apparently trivial, are not without importance in the attainment of a successful result. The patient is taught to inspire deeply so as to bring the spray in direct contact with the irritated mucous membrane of the bronchial tubes. If he should exhibit a tendency to involuntarily arch his tongue up against the roof of the mouth he is told to protrude it so as not to obstruct the entrance of the atomized fluid into the air passages.

Any fluid which may accumulate in the month he is directed to spit out as it is found by experience that if swallowed it is apt to give rise to nausea, and even vomiting. A course of treatment lasts from three weeks to a month, and even if the patient is not permanently cured he is usually relieved of his cough, the shortness of breath and other distressing symptoms soon disappear. In very obstinate cases Dr. Murrell employs in addition "Burroughs' Chloride of Ammonium Inhaler," a little acetic acid colored with tincture of litmus being added to the water in the wash bottle, to cut off any free ammonia and prevent the occurrence of spasmodic cough and bronchial irritation, which when this is neglected is sometimes caused. In suitable cases certain essential oils dropped on absorbent cotton-wool are added to the water and are volatilized with the fumes. The drugs best adapted for this purpose are pure terebine, pinol, oil of sandal-wood, oil of lemon, and oil of cubebs. Care is taken in the selection of the appropriate remedy, and it is found that the character of the expectoration is the best guide: Tar is the best drug for internal use, and is given in the form of syrup of tar, mixed with an equal quantity of syrup of Virginia prune. It is palatable and may be taken in doses of a tablespoonful in water several times a day, in fact, the oftener the better. When the expectoration is difficult it is an advantage to add to each dose five drops of a 1 in 50 solution of hydrochlorate of apomorphine, which although in large doses an emetic, acts in small doses as an excellent expectorant. Dr. Murrell speaks favorably of the "Aromatic Oil of Tar" sold in the

United States, and finds that, as a rule, patients take it well, and like it. He says that he believes it is a solution of wood tar in rum flavored with treacle. He has recently been investigating the composition of several patent medicines, and finds that "Spirone" is a 2 per cent. solution of iodide of potassium mixed with glycerine and acetone. It may be used as a spray in chronic bronchitis and bronchitic asthma. When the asthmatic symptoms predominate, Dr. Murrell employs fuming preparations, giving the preference to nitre papers made of very thick blotting-paper saturated with equal parts of chlorate and nitrate of potassium and sprinkled when dry with Friar's balsam, essence of camphor, tincture of stramonium, or tincture of senbhal. The addition of a little iodide of potassium, as in the "ozone papers," is useful. Sometimes various forms of incense are employed, the following being the favorite formula: Powdered nitre, one ounce; powdered anise fruit, one ounce; and powdered stramonium leaves, two ounces. This may be improved in suitable cases by the addition of two ounces of sunbal root, or two ounces of powdered benzoin. Cubebs cigarettes, or cigarettes made of grindelia robusta, or Hunrod's powder, mixed with Turkish tobacco, are useful and often prescribed. Dr. Murrell is also engaged in preparing a fourth edition of his work on "Massage as a Mode of Treatment."

Some days ago in passing a news stand my attention was attracted to a paper known as the "Family Doctor." Having plenty of leisure time to read, I purchased the people's medical adviser, but was startled on opening the periodical to find a good wood cut of Dr. William Miller Ord, of London, occupying the front page. Accompanying the picture of this medical gentleman was a clever but adroit sketch of Dr. Ord's life, given very minutely, even including his office location and all his movements but one. The medical man who wrote this article—and it was evidently written by one well informed in medical matters, or perhaps dictated by the doctor himself—omitted to state that Dr. Ord was in Washington during the late meeting of the Ninth International Medical Congress, but out of purely personal reasons did not attend the meeting. I have since been creditably informed that the College of Physicians, of which Dr. Ord is a member, have under consideration the investigation of this recent method of medical advertising.

Sir Morell Mackenzie, the eminent physician of the late Emperor Frederick of Germany, is preparing an official report in detail of his case, which will shortly appear here in book form. The work will only cover one hundred pages, and Sir Morell Mackenzie is to receive from his publishers the enormous sum of fifteen hundred pounds for his contribution. Seven thousand five hundred dollars, or fifteen hundred pounds, is said to be the largest sum of money which has ever

been paid by a publishing house to a medical man for any contribution.

The meeting this month, in Washington, of the Congress of American Physicians and Surgeons, has made little or no impression upon the mass of medical men throughout Europe. Now and then I have heard reference made to the meeting in a kindly manner in this and other medical centres. A very large number of eminent members of the profession in all parts of Europe have been invited, and even urged, to attend, and but few, very few, will be at the meeting, even though, I am told, suggestions have been made to many that possibly American degrees may be conferred upon many who will honor them by their presence. Unfortunately for the present managers of the Congress, the part they have taken during the past year against their own countrymen has now become more apparent here, and the reaction has been anything but favorable to them and their meeting. The suggestion, or even the promise, of degrees to be given out, which is whispered around here, may induce a few to attend the meeting, but the very many invited will stay at home.

I cannot close this brief letter without making reference to the second visit to the late meeting of the British Medical Association, of the Father of the American Medical Association. Dr. Davis was received not only warmly, but enthusiastically, and all honor was shown the late President of the Ninth International Medical Congress.

...

DOMESTIC CORRESPONDENCE.

Criminal Abortion and State Laws.

Dear Sir:—I notice in THE JOURNAL of Sept. 1, 1888, that you say in your able and instructive editorial on "The Ethics of Marriage," that "New Mexico, New Jersey, South Carolina, Texas and the District of Columbia have no laws relating to the punishment of attempts to perform abortion." As to the other States, I have nothing to say; but New Jersey in this, as well as other important matters of protection of the health of her inhabitants, is not behind any of her sister States in regard to the stringency of her laws, and he who violates in this, as the records of our courts show, gets a taste of "Jersey justice." In support of the above I send you a section from our criminal code, viz:

Section 27. "That if any person maliciously or without lawful jurisdiction, with intent to cause and procure the miscarriage of a woman then pregnant with child, shall administer to her, prescribe for her, or advise or direct her to take or swallow any poison, drug or medicine or noxious

thing, and if any person or persons maliciously and without lawful justification shall use any instrument or means whatever with the like intent, he shall, on conviction thereof, be adjudged guilty of a high misdemeanor; and if the woman or child die in consequence thereof, shall be punished by fine not exceeding *five thousand* dollars, or imprisonment at hard labor for a term not exceeding fifteen years, or both, at the discretion of the court. And in case the woman or child do not die in consequence thereof, such offender shall be adjudged guilty of a misdemeanor, and be punished by fine not exceeding one thousand dollars, or imprisonment at hard labor for a term not exceeding five years, or both, in the discretion of the court before whom such conviction shall be had."

And on this law there have been several decisions; we will name but two, to show how the courts regard it.

First. "A woman who voluntarily takes a potion administered to her for the purpose of causing an abortion, is not an accomplice in the crime of the person administering it, the law making it no crime in her to take the potion." And,

Second. "The thing administered must be noxious in its nature, but it is not necessary to prove it will produce miscarriage; the crime is complete, whether in the opinion of others it is capable of producing that result or not."

Thus you see, Mr. Editor, that New Jersey is not one of the States that *winks* at that too frequent crime, and one that some of our profession at times yield to at the appeals of the unfortunate. Hoping that in justice to the fame of our State you will give the above a place in *THE JOURNAL*, I am, Yours truly,

D. B. INGERSOLL, M.D.

May's Landing, N. J., Sept. 10, 1888.

The Report of the Medical Examining Board of Virginia.

Dear Sir:—Your editorial in the issue of September 8, on the Report of the Medical Examining Board of Virginia, should be widely read and deeply pondered. To the schools such a report is as the handwriting on the wall, "Mene, mene, tekel, upharsin;" to the profession of every State an encouragement to persevere in the good work of organizing Medical Boards.

It is not a function of the University to grant the license to practice. That the M.D. degree carries this privilege is a modern usurpation, which does not extend to degrees in other faculties. It is a function of the State, to be exercised either directly, as is done in Germany, or indirectly, by the profession organizing and appointing suitable examiners. The struggle is between the colleges and the profession, and I would refer any one who may feel doubtful as to the issue of the

fight, to an address which I delivered in 1885, when President of the Canada Medical Association (*Med. News*, 1885, ii), in which I sketched the organization of the profession in the Provinces of Ontario and Quebec, which led, in the former Province, to the complete subjugation of the schools.

You may be surprised, Sir, at these sentiments from a dyed-in-the-wool school-man, but I feel convinced that the future of medical education in this country lies largely in the establishment of State Boards, such as exist in Virginia and North Carolina, which shall (1) control the entrance examination, (2) regulate the curriculum, and (3) grant the license to practice.

Yours very truly,

WILLIAM OSLER, M.D.

1502 Walnut St., Philadelphia.

"The Ethics of Marriage."

Dear Sir:—In your editorial notice of "Ethics of Marriage," by Dr. H. S. Pomeroy, in issue of Sept. 1, you refer to "Dr. Pomeroy's illustration of plucking unripe and ripe fruit from the tree." As the illustration is as ancient as it is striking, I take the liberty of sending it as originally stated by Dr. Percival Willughby, in 1670. In a work of this date written for midwives, he says: "Let midwives observe the waies and proceedings of nature for the production of her fruit on trees, or the ripening of walnuts and almondes from their first knitting to the opening of the huskes and falling of the nutt; the greene huskes sticking so close that it is not possible to separate the huske from the shell, whilst it is unripe; but as the fruit ripenneth the huske choppeth, and with a fissure openeth, and by degrees separateth the fruit without any enforcement." This quotation, with others from the same author, will be found in the preface of "Denman's Practice of Midwifery," 1821.

Respectfully,

HUNTER H. ROWELL, M.D.

467 Prospect St., Cleveland, O., Sept. 11, 1888.

BOOK REVIEWS.

PROCEEDINGS AND ADDRESS AT A SANITARY CONVENTION held at Albion, Michigan, Dec. 6 and 7, 1887, under the direction of a Committee of the State Board of Health and a Committee of Citizens of Albion. Reprint No. 274. Lansing: 1888.

This pamphlet of 70 pages is interesting as showing what kind of papers are read at the Sanitary Conventions for which Michigan is becoming somewhat famous. Sanitary conventions teach the people what sanitation is, and show sanitary and health authorities to what extent and in

what way the public is interested in sanitary matters.

In the pamphlet before us are a number of addresses, papers and discussions, by medical and laymen. Some deal with local matters—the sanitary state and needs of Albion. This discussion of particular cases and local matters is an important point in teaching sanitary matters to the people. There are also papers and addresses on special subjects of general interest, such as "Nuisances: What they are and how to prevent them," by R. A. Martin, M.D.; "Diseases incident to the Poor," by Dr. A. G. Bruce. "School Hygiene," by Hettie Warner Bradley; "Money Value of Sanitary Work," by Rev. B. A. Brown, M.D.; "Prevention of Communicable Diseases, from the Standpoint of the Health Officer," by H. D. Thompson, M.D.; "Prevention of Communicable Diseases, from the Standpoint of the Clergy," by Rev. B. S. Taylor, M.D.; the same from the standpoint of the Lawyer, by R. Loud; the same, from the standpoint of the State Board of Health, by Dr. Henry B. Baker.

If one wishes "good literature" for the people, it can be had from the Michigan State Board of Health.

We omitted to mention the address of the President of the Convention, Rev. Z. R. Fiske, D.D., LL.D., on "Sanitation from the Standpoint of the Individual—Sanitation from the Standpoint of the State."

HYGIENE FOR BASE BALL PLAYERS. Being a brief Consideration of the Body as a Mechanism; the Art and Science of Curve Pitching; a discussion of the Causes and Treatment of the Disabilities of Players, etc. By A. H. P. LEUF, M.D., Director of Physical Education at the University of Pennsylvania and at Swarthmore College, etc. Small 8vo, paper, pages 135. Philadelphia: A. J. Reach & Co. 1888. Chicago: W. T. Keener.

Dr. Leuf is the only medical man, so far as we know, that has given any special attention to the injuries of base ball players, and what he writes is all the more valuable because he himself is an expert player. He is, we believe, one of the good curve pitchers in the country, has suffered from pitcher's sore arm, and can therefore write more intelligently of it. In America base ball has become an acknowledged occupation, and has its own special injuries and medical features. Physicians will be interested in Dr. Leuf's description and explanation of curve pitching.

A PHARMACY LAW FOR LOUISIANA.—The efforts of the pharmacists of Louisiana to secure a law in their State to regulate the practice of pharmacy have finally been successful. The last Legislature passed an act which was approved July 11, and will be in force as soon as the necessary machinery is provided.

MISCELLANEOUS.

NEW YORK STATE MEDICAL ASSOCIATION.—Programme of the Proceedings of the Fifth Annual Meeting, held at the Hotel Brunswick, Fifth Ave. and 27th St.

FIRST DAY—OCTOBER 9, 1888. MORNING SESSION, 9 O'CLOCK. ORDER OF BUSINESS.

- I. Calling the meeting to order.
- II. Announcement by the Secretary of the number of attendants from each district.
- III. Report of the Committee of Arrangements.
- IV. Address by the President.
- V. Annual Report of the Council.
- VI. Annual Report of the Treasurer.
- VII. Reports of special committees.
- VIII. Unfinished business.
- IX. New business.
 - A. Annual Reports of the Presidents of Branch Associations, in their numerical order, to be read by title.
 - B. Annual Report of the President of the New-York County Medical Association, to be read by title.

"A Case of Anesthesia by the Inhalation of Nitrous Oxide, supposed to be the first on record," by Oliver P. Hubbard, M.D., of New York Co.

"Forced Respiration: History, Apparatus, Report of six (or more) cases. Effects of, on narcotized human subjects, adaptability of, in cases of drowning or shock," by George E. Fell, M.D., of Erie Co.

"The Origin and Medical Treatment of Uric Acid Calculi of the Kidney," by William D. Garlock, M.D., of Herkimer Co.

"Railway Injuries," by Charles W. Brown, M.D., of Chemung Co.

- X. Announcement by the presiding officer that the Fellows from the different districts shall appoint two members of the Nominating Committee from each district.

XI. Appointment by the President of a member at large of the Nominating Committee.

XII. Reading and adoption of the minutes of the session.

XIII. Adjournment of the session at 12:30. During this recess of half an hour, the Fellows from the different districts shall meet to appoint the two members of the Nominating Committee from each district.

AFTERNOON SESSION, 1 O'CLOCK. DISCUSSION ON NOSOGRAPHY.

This discussion will be opened by Alfred L. Carroll, M.D., of Richmond County, with a paper in which he propounds the following questions:

Question 1. What general principles should govern classification and nomenclature, irrespective of their particularization in medicine?

This question will be discussed by M. L. Britton, Ph.D., of New York Co., and by Simeon T. Clark, M.D., of Niagara Co.

Question 2. What are the advantages of a nosographical system based upon anatomy?

This question will be discussed by Edward G. Janeway, M.D., of New York Co., and by Frank W. Ross, M.D., of Chemung Co.

Question 3. Does a nosography based upon anatomy afford satisfactory means for the registration of clinical phenomena?

This question will be discussed by E. D. Ferguson, M.D., of Rensselaer Co., by H. D. Didama, M.D., of Onondaga Co., and by Charles G. Stockton, M.D., of Erie Co.

Question 4. What place in nosography should be assigned to bacteria, ptomaines, leucomaines, and "extrac-

tives" respectively; [a] from a bio-chemical, [b] from a clinical point of view?

This question will be discussed by Elwyn Waller, Ph.D., of New York Co., by Charles A. Doremus, M.D., of New York Co., and by Nelson B. deS. Sizer, M.D., of Kings Co.

NIGHT SESSION, 7:30 O'CLOCK.

"Hiccough, with Notes on Treatment," by Frederick W. Putnam, M.D., of Broome Co.

"Diphtheritic Paralysis." "The Treatment of Diphtheria," by J. Lewis Smith, M.D., of New York Co.

"A Case of supposed Partial Twist of the Intestines," by George E. McDonald, M.D., of Schenectady Co.

"A New Treatment of Pneumonia," by Godfrey R. Martine, M.D., of Warren Co.

"Rheumatoid Arthritis," by E. J. Chapin Minard, M.D., of Kings Co.

"The Use and Abuse of the Forceps in Obstetrics," by John P. Garrish, M.D., of New York Co.

SECOND DAY—MORNING SESSION, 9 O'CLOCK.

Address on Surgery, by William H. Carmalt, M.D., of Connecticut.

"Ocular Palsies," by Alvin A. Hubbell, M.D., of Erie Co.

"Heredity in certain Classes of Cases of Chronic Diffuse Nephritis," by B. A. Church, M.D., of Otsego Co.

AFTERNOON SESSION, 1 O'CLOCK.

Discussion on Tumors. General consideration of Tumors from a surgical point of view.

This discussion will be opened by John W. S. Gouley, M.D., of New York County, with a paper propounding the following questions:

Question 1. What are neoplasms, and what are the characters which differentiate them from blastomata, and these from inflammatory processes?

Question 2. What are the advantages of naming and arranging the neoplasms in accordance with their histogenesis?

Question 3. What is the value of the anatomical basis to the clinician when the question of malignancy arises?

Question 4. What are the objections to the grouping of neoplasms in accordance with benignity and malignancy?

These questions will be discussed by Hermann M. Biggs, M.D., of New York Co.

Question 5. What constitutes malignancy, histologically and clinically?

Question 6. What is the mechanism of the necrotic process which so often occurs in certain neoplasms?

These questions will be discussed by Charles B. Nancrede, M.D., of Pennsylvania, who will also discuss Questions 4 and 13, and by Nathan Jacobson, M.D., of Onondaga Co., who will also discuss Question 13.

Question 7. What is the rationale of the recurrence of excised neoplasms in distant parts or in the viscera?

Question 8. What is the explanation of the tendency in certain neoplasms to involve secondarily neighboring lymphatic ganglia?

These questions will be discussed by Joseph D. Bryant, M.D., of New York Co., who will also discuss Question 13, by Uri C. Lynde, M.D., of Erie Co., who will also discuss Question 13, and by Leroy J. Brooks, M.D., of Chautauque Co., who will also discuss Question 13.

Question 9. What therapeutic deductions are to be drawn from the analysis of the genesis and history of a given neoplasm?

Question 10. What are the indications and contraindications of the excision of neoplasms?

These questions will be discussed by Frederic S. Dennis, M.D., of New York Co., who will also discuss Question 13.

Question 11. What is the average duration of life from the time of the appearance of a malignant neoplasm which has not been treated?

Question 12. To what extent does the excision of malignant neoplasms prolong life?

These questions will be discussed by William T. Bull, M.D., of New York Co., who will also discuss Question 13, by Charles W. Browne, M.D., of Chemung Co., who will also discuss Question 13, and by E. M. Moore, M.D., of Monroe Co., who will also discuss Question 13.

Question 13. Are malignant neoplasms ever cured?

This question will be discussed by Charles T. Parkes, M.D., of Illinois, who will also discuss Question 12, by William H. Carmalt, M.D., of Connecticut, by Stephen Smith, M.D., of New York Co., and by William S. Tremaine, M.D., of Erie Co., who will also discuss Questions 10 and 12.

NIGHT SESSION, 7:30 O'CLOCK.

Discussion on Tumors, continued.

THIRD DAY, OCTOBER 11—MORNING SESSION, 9 O'CLOCK.

Address on Medicine. "Medical New York in 1880," by John Shrady, M.D., of New York Co.

"Mechanism of Posthumous or Post-mortem Inversion of the Uterus," by Isaac E. Taylor, M.D., of New York Co.

Address on Obstetrics, by George Tucker Harrison, M.D., of New York Co.

AFTERNOON SESSION, 1 O'CLOCK.

Discussion on Puerperal Septicemia.

This discussion will be opened by Carlton C. Frederick, M.D., of Erie Co., with a paper in which the following questions are propounded:

Question 1. What facts can be cited in support of the doctrine that the puerperal febrile diseases owe their origin to the action of microorganisms?

This question will be discussed by Hermann M. Biggs, M.D., of New York Co.

Question 2. Is there a specific febrile disease peculiar to the puerperal woman, or are the various forms of puerperal fever the result of septic or putrid infection similar to or identical with that familiar to surgeons as septicemia? What etiological relations exist between the zymotic diseases and some forms of puerperal febrile diseases, and in what manner are the zymotics modified by implantation upon the puerperal state?

These questions will be discussed by Everard D. Ferguson, M.D., of Rensselaer Co., and by S. B. Wylie McLeod, M.D., of New York Co.

Question 3. What conditions of the woman predispose to the development of puerperal septicemia? To what extent are the accidents of childbirth, together with the manipulations of the accoucheur, to be considered as etiological factors in puerperal infection? Are there any antiseptic measures before, at, or after labor, under any and all conditions and complications, that may be relied upon as prophylactic to puerperal septicemia?

These questions will be discussed by Frank W. Ross, M.D., of Chemung Co., and John Shrady, M.D., of New York Co.

Question 4. Are the lesions resulting from puerperal infection always the same? If various lesions result, can an accurate differential diagnosis be made between them, based alone upon the history and symptoms?

These questions will be discussed by William H. Robb, M.D., of Montgomery Co.

Question 5. What is the pathology of each of the several forms of puerperal septicemia? What conditions or circumstances incident to puerperal septicemia, and what forms of the disease, tend to render it fatal?

These questions will be discussed by Frank Grauer, M.D., of New York Co.

Question 6. What plan of antiseptic treatment can be employed with a large degree of success in each of the several forms of the disease? Does every rise of temperature above 100° F. in the puerperal woman constitute an indication for immediate resort to irrigation? When should irrigation be intra-vaginal, and when intra-uterine?

When irrigation is employed, how often should it be done, and when should it be discontinued? What hygienic, medicinal, and dietetic treatment is to be used, in addition to the local antiseptic measures? To what extent should alcoholic stimulants and anti-pyretics be used?

These questions will be discussed by William T. Lusk, M.D., of New York Co., and Rollin L. Banta, M.D., of Erie Co.

Question 7. What sequelæ of puerperal septicæmia tend to impair the subsequent health of the woman in case of her recovery? To what extent do chronic diseases of the pelvic organs owe their origin to puerperal septicæmia?

These questions will be discussed by John G. Orton, M.D., of Broome Co.

NIGHT SESSION, 7:30 O'CLOCK.

Discussion on Puerperal Septicæmia, continued.

OFFICERS AND COMMITTEE OF ARRANGEMENTS.

John Cronyn, President, E. D. Ferguson, Secretary, *Ex-officio Members of the Committee.*

Glover C. Arnold, Chairman.

C. Ellery Denison, Secretary.

E. S. F. Arnold, Alfred L. Carroll, John W. S. Gouley, Frank Grauer, John H. Hinton, Charles A. Leale, J. R. MacGregor, S. B. Wylie McLeod, Augustus D. Ruggles, John Shady, E. H. Squibb, Isaac E. Taylor, John G. Truax, William T. White.

A STEP NEARER.—We learn that at the last meeting of the American Medical Association, an amendment to the constitution of that body was presented providing for the formation of a Section on Pharmacy and Materia Medica. The proposed amendment provides that the Section shall be organized in the same manner as the recently established Dental Section, and that reputable pharmacists may be sent as delegates by the various State pharmaceutical associations. Under the rules, the amendment lies over for action at the next annual meeting.

Our readers will remember the plea made for this movement by Dr. Cutter, and the supposed difficulties of its accomplishment, which were discussed in our columns soon after the appearance of the doctor's proposal. Notwithstanding the supposed ethical complication which was mentioned in this discussion, we hear that the prospects of the establishment of such a Section are good; if the physicians are really desirous of effecting a union with their pharmaceutical brethren, they will find a way of overcoming any such difficulties.

We hope to see the step now taken result, in due time, in establishing a relation between the two professions which cannot fail to be beneficial to both.—*The Druggists Circular and Chemical Gazette*, September, 1888.

SECRETARIES OF STATE MEDICAL SOCIETIES, prominent district and city societies, that wish to exchange, or are now exchanging their publications with those of the Nebraska State Medical Society, are asked to notify the Secretary, Dr. A. S. v. Mansfelde, Ashland, Neb., when the "Omaha Clinic," containing the proceedings of the Society, will be promptly mailed to them.

REMARKABLE FECUNDITY.—Mrs. Norman, the wife of a painter living at Fratton, Portsmouth, is reported to have given birth to four children—three boys and a girl—of whom only the girl survives. Mrs. Norman, who is about 40 years of age, is said to be the mother of twenty-one children, of whom nine are living. She had previously had twins, and seven years ago triplets.—*British Med. Jour.*

MR. CHARLES TRUAX, of the well-known surgical instrument house at Chicago, was granted sufficient time at the recent meeting of the British Medical Association to enable him to explain the merits of the Allen Surgical Pump.

THE RIGI BRAND OF CONDENSED MILK has been condemned by the Board of Health, New York City, on an official analysis showing a deficiency of from 5 to 9 per cent. of fat as compared with pure condensed milk; and all of said brand found in the city has been ordered to be seized.—*Boston Journal of Health*, Sept., 1888.

Official List of Changes in the Stations and Duties of Officers Serving in the Medical Department U. S. Army, from September 8, 1888, to September 14, 1888.

Col. Charles Page, Asst. Surgeon-General, Medical Director of the Department, will proceed to Fts. Riley and Hays, Kansas, Post near Denver and Fts. Crawford, Lewis and Lyon, Col., and return, on public business. The travel enjoined is necessary for the public service. Hdqrs. Dept. of the Missouri, Ft. Leavenworth, Kan., September 7, 1888. S. O. 114.

Lt.-Col. Basil Norris, Medical Director, will proceed to Ft. Klamath, inspect the medical department at that post, and upon completion thereof return to these Headquarters. Hdqrs. Dept. of the Columbia, Vancouver Bks., W. T. S. O. 103, September 3, 1888.

Major Daniel G. Caldwell, Surgeon, is granted two months' leave of absence from September 14, 1888. S. O. 40, A. G. O., September 10, 1888.

Capt. Fred. C. Ainsworth, Asst. Surgeon, will, by direction of the Secretary of War, proceed to Kennebec Arsenal, Augusta, Me., on public business connected with the Medical Department of the Army. On completion thereof will return to his station in this city, Washington, D. C. S. O. 211, A. G. O., September 11, 1888.

Capt. John M. Banister, Asst. Surgeon U. S. Army, is granted two months' leave of absence, with permission to apply for an extension of one month, to take effect when his services can be spared. S. O. 211, A. G. O., September 10, 1888.

Capt. Norton Strong, Asst. Surgeon, by direction of the acting Secretary of War, will report in person, at 11 o'clock A.M., October 18, 1888, to Brig.-Gen. John R. Brooke, President of the Retiring Board in session at Omaha, Neb., to give testimony in a case pending before the Board. Upon completion of this duty he will return to his proper station. Par. 9, S. O. 212, A. G. O., September 12, 1888.

First Lieut. Nathan S. Jarvis, Asst. Surgeon, is granted one month's extension of leave of absence, on surgeon's certificate of disability. S. O. 210, A. G. O., September 10, 1888.

Official List of Changes of Stations and Duties of Medical Officers of the U. S. Marine Hospital Service, for the Two Weeks Ending September 10, 1888.

Surgeon George Purviance, to proceed to Fairport, O., as Inspector. August 27, 1888.

Surgeon R. D. Murray, to proceed to Key West, Fla., September 5, 1888.

Surgeon W. H. H. Hutton, to take temporary command of Camp Perry, Fla. September 8, 1888.

P. A. Surgeon John Guitéras, to proceed to Jacksonville, Fla., after return from duty, on special train from Jacksonville to Hendersonville, N. C. September 8, 1888.

P. A. Surgeon W. D. Bratton, to proceed to San Francisco, Cal., and report to Surgeon H. W. Sawtelle for duty. September 8, 1888.

P. A. Surgeon Eugene Wasdin, to rejoin his station at Mobile, Ala. September 5, 1888.

Asst. Surgeon G. M. Magruder, to proceed to Mobile, Ala., and assume temporary charge of the Service. August 31, 1888.

Asst. Surgeon J. B. Fattie, to proceed to Memphis, Tenn., and relieve P. A. Surgeon C. T. Peckham. August 31, 1888.

Asst. Surgeon G. M. Magruder, to proceed to Way Cross, Ga. September 6, 1888.

PRESIDENT'S ADDRESS.

THE RELATION OF SOCIAL LIFE TO SURGICAL DISEASE.

Delivered at the Annual Meeting of the American Surgical Association, Sept. 18, 1888.

BY D. HAYES AGNEW, M.D.,
OF PHILADELPHIA, PA.

Fellows of the American Surgical Association:—
As the generations fare on, enriched by the results of scientific labor, which pours its tides of opulence into all departments of human thought and industry, there follow through a reactive or reflex influence, certain notable changes, not only on the life and manners of a people, but on their physical and mental diseases. The more advanced a civilization the more complex become the problems which surround it.

While the accumulation of wealth and the multiplication of appliances for human comfort have in the aggregate contributed to the well-being of the race, yet there is reason to fear, that the insatiate and ambitious demands of the masterful leaders in the work of the world, unless conditioned and environed by reasonable safeguards, may acquire their triumphs at the expense of human life. It is a suggestive and solemn thought, that in the victorious march of civilization, thousands of victims must perish beneath her chariot wheels. There really seems to be a perpetual antagonism between man's inventions and discoveries, and the well-being of a no inconsiderable fraction of humanity. He reduces the elastic vapor of water to practical use, and is rewarded by seeing countless numbers of human beings blown into shapeless masses by his rebellious servant. His chemistry creates formidable explosives, capable of dislodging the solid strata of the earth, and yet, in wicked hands, become instruments for consummating such diabolical plots as serve to unsettle the peace of a nation. He rears manufactories for fashioning multitudinous fabrics which minister to the comfort and luxury of the race, and yet while the hands of the fabricator are busy manipulating the materials of these industries, he is breathing a death laden air. We send our missionaries to China and the Sandwich Islands

to reclaim their people from the barbarities of heathenism, and then our commerce to ruin their souls and wreck their bodies. There seems, indeed, to be an external conflict between good and evils.

Considerations like these naturally lead to a very inviting field of study, namely, the relation between the material prosperity of a people and the forms of their disease. What I propose, however, in discharging one of the duties belonging to the honorable office to which, by your kind suffrages I have been elected, is very briefly to follow one line of this inquiry, that is,

THE RELATION OF SOCIAL LIFE TO SURGICAL DISEASE.

There is no tyranny more exacting or despotic than that exercised by the conventionalities which govern our living. All stages of life from infancy to old age are under its domination. It dictates the education, the manners, the walk, the dress, the forms of speech, in fine the whole being. Beyond all contradiction the behests of fashion are vastly more influential in governing public conduct, than any arguments drawn from the teachings of structure and function. As a rule, when the conflict is between taste and reason, the victory will be on the side of taste. In nothing is this more forcibly displayed than in the apparel used to protect the body. It is not an agreeable task to peep into the wardrobes or dressing-rooms of our fair countrywomen. I have no special taste for exploring museums of bizarre collections. Indeed, without a key to interpret the curious and ingenious mechanisms for clothing the form divine, such an exploration would be like an archæologist attempting Egyptology ignorant of cuniform inscriptions. I have, however, some knowledge of human anatomy in its broadest sense, and when I look upon the masterpieces of the human form, whether in marble or on canvas, a Belvedere Apollo, or a Venus de Medici, and contrast these with the dressed-out specimens of modern women, I am forced to admiration; not so much at the amazing ingenuity displayed in concealing the divinely appointed form, as at the plasticity and patient submission of mortal clay under the despotism of a conventional inquisition. Were these processes

of mutilation and abnormality harmless, did the body consist of a mere mass of protoplasm, capable under the application of certain stimuli of assuming, normally, protean shapes, the subject might be passed over with the feelings of a naturalist, but this is not so. These violations of the laws of structure bring with them serious penal inflections, which, did they terminate with the original defender, might be dismissed with a sentiment of pity. But projecting as they do, their baneful consequences to successors, they become proper subjects for criticism.

Let me name a few examples as illustrative of my subject. For some time the profession has been speculating on the causation of nasal and post-nasal catarrh, with its accompanying auditory defects, the growing frequency of which can not have escaped general observation. Doubtless no single agency will explain the presence among us of this unpleasant disease, yet there are facts connected with this affection which to me are very suggestive. I cannot recall an instance in which I have met with the disease among females belonging to the Society of Friends—Dunkards or Menonites. If this, on more extended observation proves to be true, may not the head-dress peculiar to these people be accepted in explanation of their exemption? The bonnet which at one time overshadowed the entire head, as all know, has been gradually shrinking in its dimensions, until it has become a mere shadow of its former self, and offers no protection whatever to the head. As a substitute, I would not insist upon the quaint head-gear of the Friend, though I believe that any modification which will protect this part of the body, will lessen the tendency to catarrhal inflammation of the naso-pharyngeal mucous membrane.

Muscular Restraint.—A legion of physical imperfections arises from muscular restraint. Among these may be mentioned weak ankles, narrow or contracted chests, round shoulders, projecting scapulæ and lateral curvatures of the spine. The foolish concession to appearance, and the unwise partiality of parents for enforced systems of education, the demands of which bear no just proportion to the capacity of the infantile mind, constitute the initial or determining force of these physical imperfections. In many cases the weak ankles of children, characterized by eversion of the feet, thus allowing the superincumbent weight of the body to be transmitted to the latter inside of the proper centre of support, is largely chargeable to the miserable practice of placing on the little ones, long before they are able to walk, boots tightly laced up the limbs some distance above the ankles. The confinement of the flexor and extensor muscles by this constriction, prevents that free play of movement which reacts so favorably on all the elements of an articulation; and that too, at a time when the growing forces

are at full tide, so that when the time arrives for standing and walking, the muscles are unequal to the firm support of the joint. The consequence of this feebleness is soon seen in the turning outwards of the feet, throwing the strain on the internal lateral ligaments, which in turn become elongated through growth, and thus the defect becomes established, but the evil does not terminate here. The calcaneo-cuboid and the astragalo-scaploid ligaments losing the proper support of the tendon of the posterior tibial muscle, under the abnormal tension begins to yield, and to the deformity of eversion is added that of "flat-foot." That the above is not a mere hypothetical explanation of the ankle defects, I have many times verified by finding the threatening symptoms disappear after liberating the imprisoned muscles and subjecting the enfeebled parts to a judicious massage. Under no circumstance as is too often the case, should instrumental apparatus be applied, unless in cases where from neglect, the deformity is thoroughly established and is progressive.

Take another deformity, that of bow leg. On the earliest signs of the unsightly curve, the limb is too often trammelled with irons, and the growth of the muscles arrested, when it is well known that if manual force be systematically applied two or three times a day, the limbs will gradually assume their typical form.

Again, in further illustration of our general text, take as an example a child who for one long, or two short sessions for six days of the week sits over the study desk compelled to assume a position in which from the inclination of the body the shoulders fall forward, the head being supported, most probably, on the elbows and hands. In such a posture the great serrati and pectoralis major and minor muscles are in a state of relaxation, while the erector spinæ and trapezei muscles are in a state of tension. This change in the position of the shoulders gives the scapulæ over, without antagonism or resistance, to the action of the rhomboidei and the lavatores angulæ scapulæ muscles, which acting conjointly cause that projection of the lower angles of the shoulder-blades, which the older anatomists termed "scapulæ alatæ." To all this must be added the very important factor of four to six hours in the school-room and two hours at least of home preparation for the following day's recitations, during which time the respiratory functions having been reduced to a minimum of activity, the muscles of the chest are comparatively passive and aeration of the blood tardy. Certainly no combination of conditions could be better devised for forming contracted chests and round shoulders. It is not long before the watchful eye of the mother detects the change in the figure of her child. She will probably discover this and take alarm, even when the pale face, the languid air and the capricious appetite

of the child cause no anxiety; and then comes the second act in the drama of physical deterioration, namely, a resort to shoulder-braces and stays, in order to accomplish that which the muscles should be taught to do without restraint or incumbrance.

Lateral Curvatures.—While it is true that lateral curvatures of the spine depend upon causes both central and peripheral, yet in no small number the deformity is clearly attributable to influences of a social nature. The young column, by reason of the non-union of the epiphysis and diaphyses, and the supple character of its ligaments, is extremely flexible. Whatever, therefore, destroys the muscular equipoise, however inconsiderable the force, if persistently repeated, changes the centre of gravity and develops primary and compensating curves. For six months in the year, any fine morning groups of young children may be seen plodding along our streets with a miniature library of books suspended from one shoulder. To the already preponderating scale of the balance, add the additional factor, a probably badly arranged light, compelling these little *savants* to assume a lateral inclination of the body in order to obtain the necessary illumination of the subjects of the study, and you have all of the conditions necessary for perpetuating the lateral deformity. "Just as the twig is bent, the tree's inclined." As in the case of round shoulders, so here in order to prop up the falling column, instrumental contrivances are immediately called into requisition. The body is encased in a formidable coat of mail, to be followed by muscular atrophy and permanent distortion of one of the otherwise most beautiful pieces of mechanism in the human frame. It is true that in most educational institutions for the young provisions are made for physical culture and these are in some measure antidotal to the evils complained of, but in my judgment do not at all compensate for that free unstudied romp in the open air, untrammelled by the hard and fast rules of calisthenics, so fascinating to the young child. Nor does the evil end here. While the forcing process which is to stimulate the mental powers far beyond the real capacity of the immature and growing brain to receive is in progress another is inaugurated which is to qualify, especially the female child to acquit herself with distinction when the time arrives for entering the great world of society, or as Thomas Brown would style it, "for the frivolous work of polished idleness." The gait and carriage must be reduced to prescribed rules, the voice toned down to a drawl, or trained to move like a mountain torrent. The muscular apparatus of the face must be taught to express, not the spontaneous and natural outflow of feeling which wells up from the magic chamber of the heart, but rather to produce an effect; and so this work of transformation goes on until it culminates in the full-blown society

girl. Is it any wonder that under such a scheme of education, conducted throughout by a studied disregard of both the physical and mental constitution and exercising as it does such tremendous drafts on the nervous system, that the world is becoming filled with a class of flat-breasted, spindle-limbed young women, unfitted for the varied and responsible functions of womanhood, qualifications too, which under a different regimen and directed into proper channels would exert a most potential influence on all the great social and moral problems of the age.

While thus plain spoken on the frivolous methods of living, I do not wish to be understood as being unfriendly to the highest cultivation of the mental and physical powers if conducted on lines in harmony with the organization, nor to any technique which may conduce to personal grace or elegance of manners, so that the manly or womanly personality of the individual be not sacrificed to the Moloch of sentiment and sham. Indeed, indifference to these things is inexcusable in either man or woman, as not only lessening their influence in the world, but in many respects disqualifying them for the highest discharge of the duties of modern life. Valuable as may be the unpolished diamond, yet it is only after the wheel of the lapidary has worn away the dull incrustations that its true brilliancy is revealed and the gem is fitted to adorn the brow or the breast of beauty.

Bodily Constriction.—In the further discussion of my subject, I may next notice the evils of visceral displacement and pressure consequent on abdominal constriction. Whatever may be said in regard to Greek and Roman life, the infinite care which these people displayed in developing and maintaining the very best type of the human form is worthy of admiration. The Ionic "chiton" spoken of by Attic writers and so often represented in the bronzes of Herculaneum, while it would not exactly satisfy the modern idea of dress, was at least free from the charge of interfering with the contour of the human figure. The painters and sculptors of those classic days were reverent students of nature. The delineations were true to life. Their works furnish us with no hour-glass contractions of the human body. The constriction of the waist operates injuriously on both the supra- and infra-diaphragmatic organs. Any force acting on the base of the thorax and preventing the expansion of its walls, concentrates the function of respiration, which should be general, on the apices of the lungs, and hence under these circumstances the movements of breathing are for the most part confined to the summit of the chest. As the initial seat of tuberculosis is located at the upper part of the lungs may not the inordinate work entailed on these parts by constriction have some part in hastening such composite in the female where the predisposition

exists? It is this forcing inwards of the costal border of the thorax which causes the grooves on the anterior surface of the liver so familiar to anatomists. This pressure cannot fail to interfere with the descent of the diaphragm, and with the functions of the gall-bladder and duodenum, and exercises no small degree of influence in favoring the formation of biliary calculi, females being peculiarly prone to such concretions. The extent to which the liver may be damaged by extreme constriction of the waist, is well illustrated by a case quite recently reported in the *British Medical Journal*, in which a considerable portion of the left lobe of the liver had been separated from the right, the two being connected only by a band of connective tissue, and which enabled the operator to remove the detached mass without difficulty. The evil effects of this constriction of the viscera of the abdomen and pelvis, is most strikingly witnessed in the embarrassed portal circulation, in the different uterine displacements, elongation of ligaments, displaced ovaries, tubal inflammations, hæmorrhoids, hernia and other morbid conditions which either prevent or disqualify the woman for the exercise of those functions of maternity, and which in addition, through reflex influences, entails a host of functional disorders reaching into every avenue of the body and invading both the mental and moral constitution of the victim. So prolific have these infirmities become that a new department of surgery has been organized for their special management. To what, if not to social causes, can these morbid changes of structure in the pelvic organs, especially of the uterus and its appendages, be attributed? Why should laceration of the cervix uteri be so common an accident? Labor is a natural process and ought not under ordinary circumstances be attended by lesion of uterine tissue. I can conceive of no agency more likely to induce that muscular degeneration which predisposes to this accident than the modes and methods of modern living, especially among the inhabitants of great cities. In the expression "modern living," much is embraced. It includes culinary pharmacy, over feeding and drinking, insufficient or injudicious exercise, improperly heated apartments, and a disproportion between the hours of exercise and rest. Contrast, if you will, the muscles of the hardy country housewife, who bearing the cares and responsibilities of a dependent family, bustles about the livelong day, in-doors and out-of-doors, eats with a relish her plain and simple fare, repairs at seasonable hours to bed and sleeps the sleep of the beloved, undisturbed by dyspeptic nightmares and rising with the golden dawn resumes the round of domestic toil with a clear head and supple limbs; I say, contrast this type of a class with that of another, the woman born to luxury and ease, whose capricious and exacting taste taxes the art of the professional caterer,

who drags out the morning hours toying with some crazy piece of embroidery or trashy novel, lunches at one, rides out in the afternoon for an airing of two or three hours, returns to a dinner of five or six courses at seven, completes the evening at the opera, the theatre or the assembly, and coming home after midnight, crawls into bed weary and exhausted in body and mind, only to rise with the best hours of the morning gone, for another day of aimless routine life. Can it be doubted that in the first case, with a digestion unimpaired, with the products of textural change consumed by functional activity and eliminated through the proper excretories, the woman should possess a vital resistance and a tone of tissue altogether superior to that of the other, whose habits of living must necessarily favor their faulty metamorphosis?

To these same agencies must be attributed that brood of nervous and hysterical evils for the relief of which the gynecologist, too often I fear, invades the domain of womanhood, around which her whole sexual nature revolves, and which, save only in the direst extremity, should be sacred against all operative intrusion.

Late marriages constitute another social evil, the penal inflictions of which involve both sexes alike. Pride and luxury determine long engagements or deferred proposals. Marriage, it is believed, necessarily involves an establishment, a display, a retinue of servitors. The good old notion of two souls being united in wedlock for the purpose of being mutual helpmates, and patiently together working up from modest beginnings to affluence, seems to be entirely at variance with the modern idea of this relation. In the meantime the young man is betrayed into unlawful sources of gratification, alike destructive to moral and physical purity, the pollution of which incontinence is often subsequently communicated and perpetuated to wife and offspring. I would not dare to say how many cases of this nature have been entrusted to my professional confidence, though I doubt not my experience does not differ from that of many of my professional brethren whom I now address. It is under such circumstances that many of those infective inflammations of the Fallopian tubes, as salpingitis and pyo-salpinx, arise and which entail the most serious deterioration of health.

The Foot and the Shoe.—It may be thought by some persons that the subject of the foot and the shoe is not of sufficient dignity to appear in a public address. The Romans and the Greeks thought differently. The literature of both peoples is full of references to the shoe worn by both sexes. So important, indeed, are the feet to the well-being of the body, that whatever impairs their usefulness, either for support or locomotion, becomes a positive calamity. Nothing can be more unlike the human foot than the modern

shoe. Let any one leave the impress of his or her foot in the wet sand of the sea-shore and then place alongside of the imprint a fashionable shoe; that the two were ever intended for each other would scarcely strike a child of the forests. The North American Indian entertains juster notions about clothing this portion of his body than does the civilized denizen of New York or Philadelphia. Compare the moccasin with the shoe of the city belle. Compare the *ζανδαπλιον* or the *πεςδύχια* of Pollux or of Aristophanes with the same and we shall see that the savage and the polished Greek alike understood the value of sound feet in the race of life. It is the imperfect adaptation of the shoe to the foot which constitutes the fruitful source of tired ankles, corns, bunions, overlapping of the toes and in-growing nails. Some idea may be formed of the magnitude of the evil from the fact that of 800 patients under the care of a prominent chiropodist of Philadelphia, the great majority of the defects were entirely attributable to the high heels and the contracted toes of the shoes. Especially do these physical encumbrances arising from a blind submission to social laws operate disadvantageously to our fair women at the beginning of the new dispensation requiring both muscles and brains, and when her friends propose to sweep away all the old traditions and claim for her the earth with all its masculine employments.

Games and amusements which in themselves are proper and praiseworthy too often become developed into a craze, working both moral and physical mischief. Professor Leuf, himself a professional in the national game of base-ball, has described the pitcher's arm, a condition of over-taxed function and one in which all the anatomical elements of the upper arm are involved. There is also the tennis-arm and the swollen, supersensitive prostate of the bicyclist, both due to the abuse of popular amusements.

Defects of refraction or visual defects constitute another class of affections fairly attributable in many instances to social influences. The number of children which may be seen in our streets any day wearing glasses has become a matter of common observation. It is far from being probable that the most exquisite piece of mechanism, the human eye, came from the Divine Artificer imperfect. Because eyes are young, it does not follow that they are thereby better fitted to sustain prolonged use. Just the reverse is true, and it is high time that parents and educators begin to recognize the fact. The power of the eyes for continued use, like that of other organs of the body, is one of gradation. It moves in the general procession and strengthens with the advance in life until development has attained to its zenith. Not only so but, the eye being a part of the body, it must suffer or rejoice through the operation of general causes. A bone may have its normal curves changed, a tendon may slip from its ap-

pointed groove, or a blood-vessel may be destroyed, and yet very little disability be realized; but the eye is made up of such extremely delicate structures and acts according to such fixed physical laws, that not the slightest alteration of a curve or the mobility or density of its media can occur without great vitiation of function. To exact, therefore, long hours of study from children of a tender age, involves a degree of functional strain altogether disproportionate to the structural resources of the organ and, by disturbing the orderly processes of nutrition, gives rise to hypermetropia, asthenopia, astigmatism and its companion headache. That the picture is not too highly colored or the causation overstrained, we have only to contrast the children born and reared in those portions of the country not too much dominated by the methods of modern civilization, and who rarely demand a resort to artificial aids to provide for abnormalities of vision. The only remedy for the evil where infantile scholarship is insisted upon is the Kindergarten or object system, the most natural and effective method of impressing the young mind.

Renal Disease.—Is there any reasonable explanation drawn from sources of a social nature for the great frequency of those renal disorders which come more particularly under the care of the surgeon as crystalline deposits and calculi? For maintaining the general health at the highest physiological standard, a proper quality of food and the proper disposal of tissue waste are essential conditions. Along with wealth and luxury come the abuses of the table. Americans are fast becoming a nation of dyspeptics. Our country is so rich in the products of every zone that nowhere else in the world can you find such a variety of foods, animal and vegetable. These foods, manipulated in a thousand ways by the subtle art of the professional cook, almost necessarily betray one into excess, and also create the desire for wines and other alcoholic beverages to aid the stomach in disposing of its plethoric supply. In great cities, which furnish relatively the largest number of cases of renal disease, affecting preëminently the mercantile and sedentary classes, we find just the conditions favorable to their development. The competitions of trade keep the merchant always at white heat. Time is golden, and the street-car and other means of conveyance annihilate distance and the ride is substituted for the needful walk. A hasty lunch at the most convenient restaurant satisfies the inner man until the business of the day is closed, when, weary and worn, he is driven to his home to partake of a course dinner, the balance of the evening to be spent on the lounge with the evening paper or the latest periodical. To the literary man the fascinations of the study and the library charm him away with their siren voices from the fields and the highways, until bodily exercise grows

distasteful and repugnant. In the meantime there has been no provision made for the waste or tissue metamorphoses of the body through that great agency, exercise. These accumulate in the blood, the internal eliminating organs, of which the kidneys are chief, are overtaxed, and then follow the evils of malassimilation and of excretion, in the form of urates and oxalates, often resulting in the formation of calculi.

In conclusion, may we ever hope for a time when the race will realize that these bodies which we wear, which God has so highly honored by his own incarnation, are sacred temples to be kept in harmony with recognized physical laws, and not to be made instruments of mere animal gratification.

RENAL TENESMUS:

A RESULT OF CHRONIC CYSTITIS AND URETERITIS; SUCCESSFUL TREATMENT BY KOLPO-URETERO-CYSTOTOMY AND INTRAVAGINAL DRAINAGE COMBINED WITH ELEVATION AND SUPPORT OF THE UTERUS AND OVARIES.

Read in the Section on Gynecology, at the Thirty-ninth Annual Meeting of the American Medical Association, May, 1888.

BY NATHAN ROSEMAN, M.D.,

SURGEON TO THE WOMAN'S HOSPITAL, NEW YORK.

I read before the New York State Medical Association, Sept. 27, 1887, a paper entitled, "Chronic Pyelitis; Successful Treatment by Kolpo-uretero-cystotomy, Irrigation of the Pelvis of the Kidney, and Intravaginal Drainage." In this communication I showed that the vesical orifice of one of the ureters could be exposed by making an opening at the ureteral angle of the trigone of the bladder on the affected side, and that disease of the renal pelvis could be treated and cured by local means. In order to catheterize the ureter and pelvis of the kidney, the anterior wall of the vagina is exposed, in the supported knee-elbow or left lateral position, by the use of my dilating speculum and perineal elevator; the upper border of the artificial opening is then elevated by means of a tenaculum, and the vesical mucous membrane containing the orifice of the ureter is thus rolled out into the vagina. In this way we are enabled to guide a flexible catheter into the ureter, and thus to avoid all injurious probing of the bladder. By injecting warm water, or a solution of bichloride of mercury (1-20,000), through the catheter with a small syringe, the pelvis of the kidney is gradually filled. Distension of the organ gives rise to a peculiar pain, which serves as a guide as to the quantity of fluid which should be injected. When the water is allowed to escape, it brings

with it pus, blood, and calcareous detritus, if these irritating substances are present. The injection should be repeated every two or three days or oftener, according to circumstances, and the irrigation continued until the washings are free from sediment.

In the paper referred to I further showed the effect of this method of treatment upon obstruction of the urethra and cystitis, which are commonly associated with the pyelitis. The opening in the bladder, by affording physiological rest and drainage of this organ and the urethra, leads to the subsidence of the inflammation or irritability of the mucous membrane of both structures, and to the atrophy of the thickened muscular walls. The bladder being thus kept continually empty through intravaginal drainage, offers no resistance to the entrance of the urine as it comes from the ureters, and there is no longer a tendency to its reflux toward the kidney during expulsive efforts of the bladder. Physiological rest and drainage of the ureters and pelves of the kidneys, as well as of the bladder and urethra, consequently follow the operation. I also described several forms of intravaginal and vulvo-vaginal drainage instruments, which, by collecting the urine in a satisfactory manner and making the patient comfortable, free, in great part, the operation from its chief objections; to wit, the presence of accumulated urine in the bladder and vagina, and dribbling from the vulva.

At this time I had treated two cases of pyelitis, both of which were cured. I have since done kolpo-cystotomy and kolpo-uretero-cystotomy eight times.² Having thus a ready means of access to the bladder, ureters, and pelves of the kidneys, I have learned, by observation and experiment upon the living subject, some new and important facts concerning the diseases of the upper urinary organs in women.

Anatomy and Pathology.—In presenting the results of these investigations, I have selected as my subject "Renal Tenesmus," a frequent result of chronic cystitis and ureteritis, in contradistinction to pyelitis, the usual result of urethrocele, cystitis, and ureteritis. It is the most characteristic symptom of the class of cases of which I wish to speak. I have chosen this symptom rather than a pathological condition, as I wish to make it prominent, because it is the first and frequently the only indication of the gradual extension of urethral and vesical disease to the ureters and pelves of the kidneys. From the peculiarity and wide range of the group of symptoms embodied in the use of the term renal

²I have now performed thirteen operations in all, combined with intravaginal drainage—two of kolpo-cystotomy, and eleven of kolpo-uretero-cystotomy. Two of these operations were for urethrocele and cystitis, one was for left pyo-nephrosis with dilatation of the ureter, one for left pyelitis with sacculization of the ureter, three were for pyelitis with dilatation of the ureter, and five for renal tenesmus, without dilatation of the ureters, or pelves of the kidneys.

tenesmus, it is liable to be confounded with pyelitis, with which it is closely allied. I mean to designate by this term a distinct manifestation of morbid irritability, without pathological evidences of inflammation other than that of pain. The distinction between it and pyelitis, resulting, to a certain extent, from like causes, cannot, I conceive, be too sharply drawn.

Here, as in other parts of the body, the progress of disease is inward—from organs communicating directly with the exterior of the body, and exposed to injurious influences from without to those in more sheltered positions in the interior. It is true that an abnormal condition of the urine sometimes leads to the formation of renal calculi, or the ureters and pelves of the kidneys may be pressed upon by abdominal tumors, be the seat of a new growth, or be implicated in disease of neighboring organs, and in these conditions renal tenesmus may occur as one of the symptoms; but as I have approached its study from the urethra and bladder, I will at present consider it only in its relations to disease of the upper urinary passages following affections of the urethra and bladder.

That an inflammation of the mucous membrane of the urethra and bladder should extend to the vesical extremity of one or both ureters is not surprising. The mucous membrane lining the ureters is continuous with that of the bladder, and the ducts traverse the vesical wall for an inch and a half. It is therefore probable that in an acute cystitis, preceded or not by urethritis, the vesical part of the ureters rarely escapes. As a rule, when the inflammation of the bladder subsides the ureteral mucous membrane returns to a normal condition. But if urethrocele should co-exist, or the walls of the bladder should become hypertrophied, or there should be distortion of a ureter arising from the pressure upon it of a displaced uterus or ovary, or both, or of pelvic growths of any kind; why, then, the disease of this portion of the duct is not only liable to continue, but it will sooner or later extend to the pelvis of one or both kidneys, under the form of pyelitis, or of renal tenesmus.

Cystitis more or less localized in the base of the bladder, complicated by ureteritis, is a more obscure but highly interesting condition. The cystitis commences as a local or general inflammation, and afterward becomes confined to one locality in consequence of the retention of residual urine due to sacculation of this part of the bladder. Pouches in the base of the bladder may result from irregular thickening of its muscular coat or from distortion of the vesico-vaginal septum, in consequence of the presence of cicatricial bands and contractions in the vagina, or, as I have more frequently observed of late, from fixation of the uterus in an abnormal position. There is frequently, in these latter cases, lateral

displacement of the uterus, and the cervix is drawn upward and outward toward one or the other side of the pelvis, carrying the vesical wall with it, and becoming there more or less fixed. In this way is produced a funnel-shaped pouch, the apex of which corresponds to the attachment of the cervix to the bladder. A fold in the vesical wall also occurs in cases of backward displacements of the uterus, especially in well-marked retroflexions with inclination of the fundus to one or the other side of the pelvis. The bladder is attached to the anterior aspect of the cervix uteri along a line about an inch in length. When the fundus uteri sinks into Douglass' cul-de-sac and the utero-vesical pouch of the peritoneum is thus effaced, the highest part of the attachment of the uterus to the bladder is drawn backward, the lowest is displaced forward by the cervix, and the superior wall of the bladder approaches the base. In this way, instead of the regular and rounded form of the cavity of the bladder, at this point is produced a more or less acute angle, the apex of which corresponds to the highest point of the utero-vesical attachment, and consequently the deepest and narrowest part, to the side toward which the uterus is inclined. Frequently, these folds and distortions of the vesical walls are very distinct, and the artificial opening in the bladder, the result of the operation of kolpo-uretero-cystotomy, affords an excellent opportunity for the study of the mechanism of their production. One of the ureters may empty into a pouch produced in some one of these ways, and thus the inflammation may extend to its lining membrane. The distortion of the bladder at this part also favors the reflux of urine into the duct during expulsive efforts. Fixation of the uterus also, even when the organ is in a normal position, by interfering with the mobility of the bladder, prevents its easy and symmetrical dilatation by the urine and the complete evacuation of its contents. These influences must be studied all the more closely, because, although great irritability of the bladder and renal tenesmus exist, sometimes there is no pus in the urine, and at others only a very small amount. Exacerbations, however, occur, especially during the menstrual periods, when the inflammation extends to the entire vesical mucous membrane and the urine contains large quantities of pus.

Ureteritis may remain localized in the vesical portion of the ureter, or the inflammation, from an increasing urethral, vesical, or uterine lesion, may extend upward and involve the pelves of the kidneys. In my experience this extension is either preceded or accompanied by dilatation of the ducts. When I have opened the bladder and exposed the ureter, in those cases where the inflammation was confined to its lower part, the lumen of the duct was contracted in consequence

of thickening of its coats or of morbid irritability in its entire extent, associated with uterine and ovarian displacements, which there is reason to believe are almost, if not always, present under such circumstances. In the cases of pyelitis which I have treated, on the other hand, associated also with uterine and ovarian displacements, the ureter was considerably dilated. The cause of the dilatation of the ureter and at the same time the extension of the inflammation is, as I believe, the reflux of the urine bearing septic material from the bladder, arising mainly from the increase of obstruction in the urethra to the outflow of the urine. Thickening and narrowing of the urethra, distinguishing features of urethrocele, by necessitating forcible efforts of the bladder to expel its contents, lead to concentric hypertrophy of the muscular coat and increase the strain upon the ureters, thus causing pyelitis. Partial or general thickening of the muscular fibres of both these structures, the result of overaction in irritable bladders arising from recurrent attacks of cystitis, produces the same effect by increasing the power of the contractions of the bladder. At the same time these contractions occur with greater frequency and longer duration, thus leading to renal tenesmus, as I have observed it in connection with the various forms of uterine and ovarian displacements just described.

Classification.—Now, from the foregoing anatomical and pathological considerations, the chronic inflammatory affections of the female urinary passages may properly be divided into four classes, namely: 1, Urethritis; 2, cystitis; 3, ureteritis; 4, pyelitis. The progress of development is from without inward, and the order of occurrence, as I believe, is the one enumerated.

Urethrocele and Cystitis.—The following extract from a paper³ I read before the Medical Society of the State of New York, will show the scope of my views upon urethritis and cystitis at that date, and will serve at the same time to connect these views with those I at present entertain upon the pathology and treatment of the chronic inflammatory diseases of the upper urinary passages belonging to the third and fourth classes of our division, namely, ureteritis and pyelitis to be referred to again:

"The starting-point of urethral and vesical lesions in the female is to be sought in the lower half of the urethra, closely related in front with the triangular ligament and blending behind with a spongy erectile tissue of the vagina.

"The calibre of the urethra may be transiently narrowed by congestion of its mucous lining, or permanently narrowed by infiltration of coagulable lymph into the underlying cellulo-elastic tissue, which constitutes properly the so-called

organic stricture, as in the male, and which, however seldom met with, is liable to the same sequences.

"Infiltration into the spongy erectile tissue outside the urethra, by plastic lymph, is, I believe, by far the most common beginning of the morbid process, whatever be the cause that produces it. This interrupts the stream of urine, either by encroaching on the calibre of the urethra, or by deflecting it beneath the triangular ligament, both cases being attended with more or less dilatation above.

"The next step in sequence is increased functional activity of the urethral muscular coat in overcoming the obstruction to the flow of urine. The result upon its structure is hypertrophy, and this will be of the eccentric type, thickening the urethral walls, while enlarging the calibre. Hence the ease with which large catheters of a proper curve pass at all stages of the disease. False and true hypertrophy here coexist. The true hypertrophy increases *pari passu* with the muscular contraction, and is followed by still greater distortion of the canal at an angle more and more acute as it turns the triangular ligament, and with corresponding contraction of its walls at that point. This mechanical impediment below coincides with the increased weight and volume of the stream of urine above, to put the walls of the urethra on the stretch in the upper part of its course.

"Thus is gradually formed the urinous tumor, which drags down in front the adjacent vaginal wall, appearing as a prolapsus between the nymphæ, and filling up the ostium vaginae.

"The looser attachments of the urethra to the vagina in the upper part of its course facilitates this result. Such is the condition of the parts to which I apply the term *urethrocele*. Often confounded with cystocele, it is really distinct.

"The arrest and retention of but a few drops of urine, at first, goes on until this may amount to a teaspoonful or more. It is then decomposed in this pocket, becomes alkaline, and by its irritation provokes congestion of the urethral mucous membrane. This congestion, extending to the vesicle trigone above, will bring white glairy mucus into the urine with vesical and rectal tenesmus. Causes favoring this extension are errors in diet, overexertion, and excessive coition. Acute cystitis resulting, first complicates the urethrocele, and is more or less decided according to the gravity of its determining cause. After a few days the active congestion disappears or subsides, with the vesical symptoms, leaving the urethrocele persistent. A few days, or weeks, or months afterward, similar provoking causes, even slighter than at first, will reproduce the congestion, while extending its area, with a corresponding increase of the severity of all the symptoms. . . . Finally, chronic cystitis overshadows the primitive urethrocele,

³Urethrocele, Catarrh, and Ulceration of the Bladder in Females. See Transactions for 1871.

although this still contributes to exacerbate the long and frightful train of evils.

"The vesical mucous membrane seems to possess almost boundless susceptibilities of irritation, and the higher this ranges, or the greater the area congested by contact with ammoniacal urine, the more is the subjacent muscular coat excited to contractions of abnormal force and frequency. Hence hypertrophy, increased congestion, blindly seeking relief by increased mucons secretion, and more active fermentation of the urine, deposits of its ammonical magnesiau phosphate, sometimes hæmorrhage into the bladder, blood extravasated into the submucous cellular tissue, or abscesses formed there.

"This hypertrophy of the concentric type, although apparently slight in the mucous coat, is more serious in the muscular coat, whose efforts to overcome the urethral impediment and rid the bladder of its acrid contents, keep it growing until it reaches an inch or more in thickness. Antopsies reveal upon its inner surface fascicles of muscle like the interior of the right ventricle of the heart. Its color is deepened by the increase of venous blood in its retarded circulation, and its consistence softened by the same cause. The circular and spiral muscular fibres of the upper urethra are also hypertrophied and overcome the former dilatation of the canal, thus converting the eccentric into concentric hypertrophy of the urethra, which has become firmer to the touch, while its urinous tumor is less defined.

"From the earliest period of vesical hypertrophy, the congestion of the mucous membrane occasions thickening with an cedematous feeling in the bas-fond, and the contraction of its pliant walls under this irritation is even greater than is possible after they have been straightened out and expanded by progressive thickening. The vesical cavity, moreover, is reduced by the pressure of the anteverted womb upon its superior fundus, which at this early stage gives it a somewhat cylindrical shape.

"On the vagina, the effects of a hypertrophied bladder are seen in the increased firmness of the vesico-vaginal septum, and the congestion and hyperæsthesia of its mucons membrane.

"Ulceration initiates the destructive stage of subacute inflammation or chronic catarrh of the bladder. It will be superinduced by the excessive hyperæmia of small or large patches of membrane, especially at the trigone and bas-fond, and by extravasations of blood into the submucous cellular tissue, caused probably by rupture of minute veins at the time of strong muscular contractions. In either event the mobility or pliability of the mucons membrane is lessened or destroyed by the inflammation which has reached its acme, and which now terminates in sloughing of the membrane (gangrene) perhaps to a very limited extent, or by an abscess opening through it into the blad-

der. It is also to be considered that the mucons membrane, rendered friable by previous inflammation, and thrown into irregular folds, may tear when it can no longer stretch under the powerful grasp of the hypertrophied muscular coat. This accident will occur the more readily on account of the anteverted position of the womb, which, I believe, always exists, and the pressure of which may explain the greater proneness to extensive ulceration of the female bladder, as averred by our morbid anatomists."

Treatment.—In further consideration of the methods and objects of physiological rest, I am led to regard all four of the inflammatory diseases of the urethra, bladder, uterers, and kidneys named as so many stages of the same pathological process. In short, if it were possible to cure the initial acute inflammatory lesions of the urethra and bladder, which rapidly become chronic, before the more internal organs are involved, the diseases of the ureters and pelves of the kidneys, thus arising from continuity of structure, might be almost, if not entirely, avoided. Hence the great importance of recognizing early commencing urethrocele and cystitis, and treating them promptly, for, if neglected long, the upper urinary passages will surely suffer sooner or later in the order of sequences previously indicated.

Kolpo-cystotomy.—Kolpo-cystotomy, to secure physiological rest of the urethra and bladder, is undoubtedly the operation indicated for the relief of cystitis coexisting with urethrocele when the ordinary remedies at our disposal have failed; not dilatation of the urethra, nor an artificial opening between the canal and the vagina, expedients at best of questionable utility.

In the early stage of urethrocele, in which there is sacculation of the canal and retention of urine, I advocated on theoretical grounds, in the paper just quoted, the establishment of an opening into the canal from the vagina, a procedure which I called "tapping of the urethra;" but I soon saw that the practice recommended possessed no real merit, for the reason that the relief of the urethra afforded by such an expedient would confer little or no immunity upon the bladder against the extension of the inflammatory process to its cavity, and I therefore gave up the idea. Dr. T. A. Emmett proposed a similar operation on the urethra, several years later, which he called "button-holing of the urethra," but from what I have seen of the bad results of this procedure in cases which had been subjected to it by his followers, I would not be inclined to recommend it, for the reason that, when drainage from either the urethra or bladder or both is required, it should be established through an opening at a favorable point in the vesico-vaginal septum, where the opening afterward can be more easily closed, and injury of the functions of the urethra be entirely avoided. A large opening made here gives relief to both

urethra and bladder by putting them in a state of physiological rest, and while they are being thus cured the ureters and pelvis of the kidneys are guarded against further strain and the risk of commencing disease.

The practice of making an opening into the bladder as a means of treating cystitis is itself of comparatively recent origin, but it is recognized generally by the profession as of great practical value. It has, however, been restricted in its employment for the want of suitable forms of intravaginal drainage, by which alone the beneficial and legitimate results of the procedure can generally be obtained. I was the first in this country, as I believe, to treat successfully chronic cystitis by kolpo-cystotomy, which I did in my private hospital in New Orleans, in 1861. My first case was one of ulceration and concentric hypertrophy of the bladder coupled with urethrocele. The mucous coat of the bladder was thickened and redundant, and had a low grade of vitality. It was exposed to great tension on account of the violent and irregular contractions of the muscular coat. From its friable condition, no doubt, it readily became fissured and ulcerated, as was shown by the very minute disintegrated particles discharged through the urethra, which I recognized from time to time with the unaided eye. The same pathology and mechanism of the walls of the bladder will serve to explain the occurrence of gangrene and perforation, not only of the mucous but of the muscular coat as well, in bad forms of recurrent cystitis, a case of which I could here cite if time permitted.

The very large opening, nearly the size of a silver dollar, which I finally made in the vesico-vaginal septum of my case referred to, afforded full and free vesical drainage, and within one year all the diseased structures were completely cured by it, and the artificial fistula closed. The cause of failure to get the good effects of this procedure, in the hands of most surgeons who have employed it since, I am convinced, is because they do not make a sufficiently large opening in the bladder.

To illustrate some of the important objections to the latter practice I will cite here a typical case—Mrs. S—, of Ohio, aged 32, who recently came under my care—in which the initial stages of urethrocele and cystitis were completed after six years, with the development, as is believed, of ureteritis in the right side in the regular order of sequences. The operation of kolpo-cystotomy was performed by one of the ablest gynecologists of New York, but, notwithstanding his acknowledged skill, the disease was only ameliorated for a time, resulting no doubt from the smallness of the opening he made and his failure to secure perfect vesical drainage. The patient, in spite of his kolpo-cystotomy, after five years of further development of sequences (April 11, 1888) was ad-

mitted into my service in the Woman's Hospital, presenting all the terrible consequences of renewed and perpetuated sufferings, with blighted hopes and ceaseless dread of death from unknown causes. I found the fistula made for drainage five years before, situated a little to the right of the median line and very near the cervix uteri, a mere longitudinal slit through the thickened and contracted vesico-vaginal septum. It would about admit a No. 10 bougie, and through it protruded a small knuckle of the thickened vesical mucous membrane. The urethra had gone through all the stages of urethrocele, from an attack of urethritis occurring four days after marriage, and the bladder was in a state of concentric hypertrophy with a retaining capacity not exceeding three ounces of water. The patient says that she did not experience any real benefit from the operation she underwent until about six months afterward, when she got out of bed and began to walk about, attributed properly by her to a free escape of the urine, in obedience, of course, of the law of gravity. The most of the symptoms in her right side, from this time on continued to improve. But this amelioration of her sufferings was only of short duration. Pains soon began in the left groin and lumbar region, and they radiated down the thigh to the knee and foot, and came on in paroxysms not unlike those of renal colic. At the end of three years (two before admission into the hospital), though relieved almost entirely of her sufferings in the right side, the paroxysms of pain in the left had already become more frequent and severe in character, which were often followed by free discharges with the urine of thick and offensive pus. This condition of things continued to grow worse and worse until she entered the hospital. She had a bad form of retroflexion and fixation of the uterus. Notwithstanding her varied sufferings of eleven years' standing, greatly aggravated no doubt from the last-named cause, I found her to all appearances in a state of robust health. But she was nervous and unable to sleep, results no doubt of the increased frequency and severity of the pains in her urethra, bladder, and left side, combined with the irritating effects of the constantly escaping ammoniacal urine. The treatment I proposed in the case was the correction of the displaced uterus and the successful establishment of intravaginal drainage, two most essential steps, I conceived, and without which I did not think it possible that any good could be accomplished toward the relief of the sufferings described.

Here the pathology and obstacles to perfect vesical drainage were not unlike those usually found in certain forms of chronic cystitis in the male subject, resulting from old strictures of the urethra, and enlargements of the prostate gland. These two diseases, as is well known, bear a direct relation to dilatation of the ureters and surgical

kidneys, which are usually rapid and certain in their developments; but they are no less constant and uniform in the production of their sequences than were found to exist in the case just cited, resulting from urethrocele and cystitis.*

* June 30th. Progress proved necessarily slow in my first efforts to restore the displaced uterus and establish satisfactory drainage, owing to the greater immobility of the organ, and consequently the greater angle to be overcome in the adjustment of my utero-vesical support than I supposed in the outset of the treatment. Notwithstanding these obstacles, however, and the restiveness of the patient, the gradually increasing mobility of the uterus and the daily improved state of her health encouraged me to persevere.

Matters thus went on until finally I became convinced that the old fistula, from the smallness of its size, and the partial closure of it nearly all the while by the existing teat-like protrusion of the vesical mucous membrane, were obstacles even more grave than those just mentioned. These obstacles, to my mind, accounted for the former persistency of the pains in the right side, and afterward the renal colic-like pains in the left. A more minute and careful examination at this juncture of the pathological anatomy of the vesico-vaginal septum, especially in the locality of the vesical orifice of the left ureter, fully confirmed my impression upon these points. Here I found the area of the structure contracted down to one-fourth at least of its original dimensions. It was thickened in about the same proportion, hard, resisting, and exquisitely sensitive under pressure of the finger and depressor. From this further study of the parts, I thought it possible that, from the incompleteness of the relief—after the operation of kolpo-cystotomy five years before—the hypertrophy of the muscular coat of the bladder had itself not only gone on increasing in the locality indicated, but that the original cystitis had been followed here by ulceration of its mucous coat as well, thus causing in this way abnormal relations of the parts, and mechanical obstruction to the outflow of the urine from the corresponding ureteral orifice. I therefore decided to perform left kolpo-uretero-cystotomy, in order to give a direct outlet to the implicated ureter, which I did in the supported knee-elbow position, on April 27th, in the presence of several physicians and the house-staff of the hospital. I made as large an opening as the restricted limits of the diseased structures would permit, leaving a longitudinal strip of tissue between the old and new openings, the breadth of the index-finger. I found the thickness of the structures fully five-eighths of an inch, and an artery in the upper border of the opening that spouted blood almost equal to a divided radial. Only by the quick application of a long pair of compression-forceps was the patient saved from excessive loss of blood. The orifice of the imprisoned ureter could not now be discovered, nor could the morbid changes of the muscular and mucous coats of the bladder under the newly-made opening be carefully examined, owing to the free oozing of the blood. Suffice it to say, that a few continuous catgut sutures in the border of the fistula at the bleeding points, and the application of a small pad moistened in a 20 per cent. solution of subsulphate of iron, controlled effectually the hæmorrhage. In this way I put the patient in the best possible condition for renewed progress in treatment by intravaginal drainage, combined with elevation and support of the uterus. As might have been expected from a fresh wound in the parts, there was for eight or ten days considerable increase in discomfort of the patient, arising mainly from flooding of its raw edges with alkaline urine. But, nevertheless, the cavity of the bladder under the new order of things soon began to enlarge, and the thickness of the vesico-vaginal septum to perceptibly diminish, thus showing that the mucous coat of the bladder had not undergone ulceration. It was not until June 3d, thirty-six days after the operation, could I find the affected ureteral orifice, and explore the tube up to the pelvis of the kidney. This I did first with a delicate probe for a few inches, and then with a French catheter, No. 8. The result was the escape through the catheter of 10 drachms of pus and urine, white, thick, and cloudy, from a point not exceeding one inch and a half up the ureter. The pelvis of the kidney and ureter were then irrigated with a solution of bichloride of mercury, 1-20,000. Again, June 5th, two ounces of a similar fluid were drawn off from a point about the same height in the ureter, containing a larger amount of pus and albumen with acid reaction, and specific gravity of 1.019. This exploration showed that when the eye of the catheter was carried into the pelvis of the kidney and irrigation commenced, it had to be withdrawn three inches from the kidney before the fluid would begin to run through it, thus proving that the sacculation was not in the pelvis, but low down in the ureter. Still again, on June 8th, with the same precautions of introducing and withdrawing the catheter through and back to the dilated portion of the ureter, three ounces of fluid of the same character were taken away, and irrigation made. The fluid drawn off this time was acid, contained pus, epithelia, and some albumen, but no casts or crystals. The catheter, now left in the ureter five hours, showed that the secreting capacity of the left kidney was equal to, if not greater than, that of the right. The temperature next day, accompanied by nausea and vomiting, rose to 103.5° F., but it gradually came down, and the irrigation was resumed, though at longer intervals. The improvement of the parts was slow but progressive to the date of this note, when the patient left the hospital to return home to recuperate her strength for future treatment, when the hospital opens in the autumn.

Remarks.—The facts brought out in this foot-note, scarcely need I say, all tend to prove the correctness of my statement in the outset, namely, that the opening in the bladder made by the surgeon who first treated the case was too small, and that to his imperfect vesical drainage is properly referred the continued development and pro-

gress of the diseases which I have found to exist in the upper urinary passages. They also forcibly illustrate the development in the same case of all four of the classes, or stages, previously described. Thus have I diagnosed in this case sacculation of the left ureter, with obstruction just above the orifice to the outflow of the retained secretions, without perceptible disease of a serious nature in the corresponding kidney, resulting from concentric hypertrophy of the muscular coat of the bladder, and constriction within its grasp, probably, of the corresponding portion of the affected ureter. Whatever may be the final result of the treatment in the case, now cut short for three months, I can at least claim thus far that a correct diagnosis has been reached, and that the domain of gynecology in this direction has been extended. It remains yet to be seen what the exact limit of such work in this new field of investigation may be, and how much further general surgery can be depended upon for the relief of such sufferings by the sacrifice of an endangered or diseased kidney, approached from the opposite direction through the resources of lumbo-nephrectomy.

One is here naturally led to ask, of what value or practical use would attempted catheterization of the ureter for diagnostic purposes have been in such a case, made through the urethra with dilatation, or, as to that matter, "free handed," without dilatation, for which it has been claimed that dexterity and supreme skill are all-sufficient? For my part I answer that it took me thirty-six days to find the ureteral orifice, and I had the advantage, too, of a window in the vesico-vaginal septum, through which I could examine and study well the inside of the bladder. I possessed in the procedure also a ready method for treating the existing inflammatory lesion in the ureter, besides being able to guard against acute attacks of cystitis.

(To be concluded.)

THE ANTIPYRETIC, AND THE ABORTIVE TREATMENT OF TYPHOID AND REMITTENT FEVERS.

Read before the Wisconsin Medical Society, June, 1888.

BY J. R. BARNETT, M.D.,

OF NEENAH, WIS.

CHAIRMAN COMMITTEE ON PRACTICE OF MEDICINE.

The search for specifics is as old as the history of medicine. From the time of Hippocrates down to the present, the highest aim of the physician has been to shorten disease by as many days as possible; to arrest, if possible, the law of its natural evolution, or so amend it as to rob it of its chief inflictions, if not its final penalty. Through all the ages it has been a hunt in the dark, the chances of success and failure being as one to infinity. Hence the alluring pursuit of the older chemists after the panacea—some substance or compound which was to fit all cases and cure all diseases. A growing knowledge of pathological

progress of the diseases which I have found to exist in the upper urinary passages. They also forcibly illustrate the development in the same case of all four of the classes, or stages, previously described.

Thus have I diagnosed in this case sacculation of the left ureter, with obstruction just above the orifice to the outflow of the retained secretions, without perceptible disease of a serious nature in the corresponding kidney, resulting from concentric hypertrophy of the muscular coat of the bladder, and constriction within its grasp, probably, of the corresponding portion of the affected ureter.

Whatever may be the final result of the treatment in the case, now cut short for three months, I can at least claim thus far that a correct diagnosis has been reached, and that the domain of gynecology in this direction has been extended. It remains yet to be seen what the exact limit of such work in this new field of investigation may be, and how much further general surgery can be depended upon for the relief of such sufferings by the sacrifice of an endangered or diseased kidney, approached from the opposite direction through the resources of lumbo-nephrectomy.

One is here naturally led to ask, of what value or practical use would attempted catheterization of the ureter for diagnostic purposes have been in such a case, made through the urethra with dilatation, or, as to that matter, "free handed," without dilatation, for which it has been claimed that dexterity and supreme skill are all-sufficient? For my part I answer that it took me thirty-six days to find the ureteral orifice, and I had the advantage, too, of a window in the vesico-vaginal septum, through which I could examine and study well the inside of the bladder. I possessed in the procedure also a ready method for treating the existing inflammatory lesion in the ureter, besides being able to guard against acute attacks of cystitis.

conditions and of the physiological resources of the system for their removal, notably by cutaneous, renal and intestinal excretion, threw some light upon the search, and so it went on, and as the centuries went by, though hardly with them, one by one a specific was found, and for this malady and then that a revision of prognosis had to be made, and a rewriting of its mortality tables had to be attended to.

Scientific medicine has seldom disdained to join in the chase empiricism led blindfolded; not always discovering more with her open eyes than empiricism would stumble upon in the dark; but she has oftener been content to accept the dictum that most maladies are self-limited and essentially unalterable in their evolution, and that medical treatment is powerless to do more than mitigate their severity.

But of late years a new science has propounded to medicine a new problem. Bacteriology has come to the aid of the pathologist and, by revealing causes of disease hitherto only dimly surmised, has not only sanctioned the old pursuit of what often seemed a chimera, but has led it into wider fields and for larger purposes. It has also imposed new responsibilities. It is not enough now to cure the sick man, or help him to survive his sickness. It is demanded that the specific cause be determined at the outset and stamped out before the germ has taken root; or, when this is impossible with the existing knowledge of pathological microorganisms and their appropriate germicides, the alternative is suggested, when practicable, of so sterilizing the soil in which they have implanted themselves as to inhibit their development, or, again, of rendering innocuous to their host the cadaveric substances their life, development, death and decay have engendered.

It is not necessary to point out the eagerness with which the medical profession has entered upon the solution of this problem, which the success of surgical antisepsis seemed to promise as so easily practicable; but it is certainly not reassuring to contemplate the wide differences in results. Still, it is well to reflect that medical antisepsis has its limitations which surgical has not. The latter is purely local in its purposes, being addressed only to the open wound, which alone is vulnerable to the attack of the surgical microbe, and which will bear without danger the presence of antiseptic agents which, if introduced into the general circulation, would prove speedily fatal. Without this limitation imposed by the paramount consideration of the patient's safety, it is highly probable that most, if not all of the specific diseases would have an aborting remedy in corrosive sublimate, or carbolic acid, or iodine, not less sure in result than they prove in the field of surgery. And with this limitation, their effect upon the normal evolution of some diseases is such as to entitle them, with few qualifications, to the name of specifics.

Standing easily first in the interest of the profession in the search for a practical and reliable germicide is typhoid fever. This would be expected from the wide diffusion of the disease over both hemispheres, and its great fatality. More than this, the universal acceptance of the doctrine of its bacillary origin has afforded a common ground on which all investigators can work in harmony to a common purpose. It is true all are not agreed as to the identity of this specific microorganism; nor is it essential that they should be. There is no reason to believe that these organisms differ so widely in their resistance to germicides that the practical physician should be called upon to declare his adhesion to Klebs and his *bacillus typhosus*, or to Wernich and his evolutionized *bacillus subtilis*, or to any other bacteriologist possessed of any other bacillus. It is enough for him to know that some specific germ gains access to the circulation—some microbe develops, multiplies and dies; profoundly affecting the vital forces by its existence within the system, or by the products of its own vitality, or its own dissolution. This affords the basis for a rational search for some antidote to the disease—that is, for some agent inimical to the existence or development of the microorganism, or eliminative of the products of its vital activity and decay, or both. And so, upon this belief upon *some* infecting microbe as the cause of typhoid fever, has been built the goodly edifice of specific treatment as it stands to-day. The calomel of Ziemssen, the iodine of Prof. Davis, the carbolate of iodine of Bartholow, the bismuth salicylate of Desplats, the ammonium salicylate—and even corrosive sublimate, claim attention here—all embody the common aspiration for some remedial agent as hostile to the bacillus of typhoid as is the sublimate to the micrococcus of wounds.

Fairly a part of this treatment, though falling short of its entire scope, may be reckoned antipyretic and local antiseptic medication; the former with the view of lessening tissue metamorphosis—though some count this as only an incident of a general antisepsis—the latter with the view of disinfecting the contents of the intestinal canal, poisoned both by the products of intestinal excretion and glandular and epithelial detritus thrown off by the ulcerated Peyer's patches, and liable to a reabsorption into the general circulation.

Remotely allied to the former is the abstraction of surface heat by the protracted cold bath—happily in disuse in this country, and cool or tepid sponging of the surface. The typical antipyretic remedies are antipyrin, antifebrin and the salicylates, and the customary choice of them is probably in the order in which they are named, with a growing partiality for antifebrin. This and its older relative have somewhat revolutionized the hospital treatment of typhoid fever throughout America and Europe, and, conjointly with proper

eliminants and stimulants, may be said to constitute the hospital plan. Judging it as such, it should be considered with the respect due such authority. As such, perhaps it is the best that the existing state of knowledge admits of. But judging of the respective merits of different lines of practice proposed upon anything less than a comprehensive view of all the conditions involved would be liable to lead to wrong conclusions. That it has led to wrong conclusions and to wrong methods in general practice seems to me quite certain. Typhoid fever is almost *sui generis* in this, that its proper hospital treatment affords no safe criterion for the guidance of private practice. More than any other disease it has its distinct epochs, which claim distinct consideration. It is the usual fortune of the hospital to receive its typhoid patients after the great therapeutic opportunity has passed for good; that is, after the epoch of glandular infiltration and ulceration has been attained. Here abortive treatment is out of the question, and no thinking physician would attempt it, realizing that now only the resources of expectancy remain. Not the expectancy of inaction, for its resources are as specific and defined as any agency for the abortion of the fever; nevertheless, that expectancy which admits the impossibility of shortening its course. What remains to it now is to retard tissue change, and thereby restrain excessive heat; the promotion of elimination through all the available emunctories; disinfection of the contents of the bowels, and nourishment and stimulation, to carry the patient to a more or less remote convalescence.

The mistake of general practice is to imitate this treatment from the beginning to the end of the malady, thereby not only missing the chance of aborting it, but positively adding to its dangers by the too prolonged exhibition of antipyretics by no means harmless when restricted to the shortest possible period.

For intestinal disinfection and elimination, and even for general antiseptis, calomel seems to be growing again in favor; though there are many who hail its renaissance with great satisfaction who do not accept the opinion of Ziemssen that it is the only remedy deserving the name of specific. But calomel was a standard and, with many, the only remedy, long before the bacillus of typhoid was discovered, or a germicide and antiseptic treatment conceived of; and the elder practitioners, who remember the failures and disasters which, by their own confession, overweighed its benefits and at length determined its abandonment, will be slow to believe that a new-found bacillus can rehabilitate an oldtime discredited remedy, even if it prove to be a germicide. These may give it a subsidiary place in the treatment of expectancy, but they will look for specifics among agents which, whatever their promise as microbicides, are happily without a history as

odontocides, and are fairly above the suspicion of homicide.

If some, to whom this record of past failure and disappointment is not a personal reminiscence, should resort to calomel for its specific results, they would doubtless do well to follow the example of Liebermeister, Traube, and others equally conservative, and limit the dose to 8 or 10 grains daily, for three or four days only.

The great importance of the subject demands a further reference to a point to which allusion has already been made: the danger attending the use of antipyrin and antifebrin in private practice. Admitting that in hospital practice, where the patient is under constant supervision, this danger is so slight that it can be disregarded, I believe that where his environment is less favorable, and especially where his remoteness from medical aid leaves him to the chances of the daily or less frequent visit of his attendant, the routine use of either of these remedies, in doses at all adequate, would be attended by a peril, both near and remote, out of all proportion to the benefits expected from them. Whether or not, as claimed by many, they produce changes in the crisis of the blood, and even in the parenchyma of organs, more or less permanent, certain it is they produce temporary conditions of grave and alarming significance, and with a suddenness no ordinary prudence can forestall. Sudden cyanosis and collapse are occasional results common to both, and these phenomena have been reported by competent observers so many times that to disregard these repeated warnings is, to say the least, censurable.

The effects of antifebrin have been scrutinized with especial care, both from the standpoint of the clinician and the pathologist, and the verdict of the profession seems to be stated by Dr. J. Solis-Cohen when he says that it is much more dangerous than antipyrin. He goes so far as to say that when even the small dose of 3 grains is given in a case of typhoid, the patient should be revisited in an hour, and before another dose is given. But he has the further objection to it that, while permitting a frequent and sudden rebound of temperature, it does nothing, on the other hand, to shorten the course of the disease.

Dr. F. M. Bauer, of New York, has several times seen cyanosis follow three or four $\frac{1}{4}$ gram doses, and Dr. Doll, of Berlin, describes a case characterized by extreme pallor and coldness of the surface, rapid respiration and violent heart-beat, general numbness and final unconsciousness, from a small but unknown dose; the patient recovering the next day.

Prof. Bokai, of Klausenburg, has determined, after a long series of experiments, that an 0.5 per cent. solution of acetanilide, with 0.6 per cent. solution of salt, dissolves the red corpuscles of the blood in man, the rabbit and the dog; and he is of opinion that this occurs in some degree in life,

when the drug is given in medicinal doses. This, he thinks, partially accounts for the diminished production of heat; but this is determined more by the paralysis of terminal nerve filaments and of the muscles themselves, and when this paresis affects the muscles of respiration, cyanosis follows.

Herczel's researches, both experimental and clinical, led to the discovery of profound changes in the blood. Under large doses the blood of dogs became reddish-black, and gave evidence of the presence of methæmoglobin, hæmoglobin being diminished 10 to 18 per cent. Also, a quantity of dissolved coloring matter was present in its serum, while its alkalinity was somewhat reduced. The clinical results correspond. Many of the phenomena of aniline poisoning attend its use, and if this is continued four to six weeks, in quantities of 30 to 45 grains daily, the dissolution of the coloring matter of the blood becomes quite manifest.

Dujardin-Beaumetz arrives at similar conclusions, both from his own observations and the experiments of others. He remarks that "the toxic effect of acetanilide seems to be to rob the blood little by little of certain principles essential to calorification, causing thus a progressive refrigeration which is incompatible with life." He cites the investigations of Lepine and Weill to prove this, but admits that the latter took 4 grams at once without any obvious effect whatever. Nor does he overlook the changes in the crisis of the blood already alluded to, pointing out that *pari passu* with the diminution of the hæmoglobin, methæmoglobin appears, as indicated by its characteristic ray in the spectrum.

This distinguished observer has other objections to acetanilide as an antithermic which, perhaps, affect the question under discussion more directly. Remarking that it disappears absolutely in the system, so that no trace of it is found in the excretions, he complains that it is of moderate and unequal energy, while practically devoid of antiseptic properties. Furthermore, he declares it to be very inferior to antipyrin as an antithermic, and so resembling phenic acid that, like the latter, it should be discarded as an antipyretic.

A paper read by Dr. George N. Acker, of Washington, before the District of Columbia Medical Society, two years ago, surveys briefly but comprehensively, and very conscientiously, the literature of antipyrin in fevers, and gives the results of his own experience with it in his service as attending physician to the Children's Hospital. He quotes the large experience of Jahn in its favor; that of Macknew, Ernst, May, Burrs and others, for and against, showing that to offset its tolerably uniform antipyretic effects there stand the objections that such effects are liable to be quite evanescent, and to be attended with functional and organic disturbances varying all along from the cutaneous exanthem to cyanosis and collapse, and

even to sudden death, as in the case of Burrs, where the autopsy showed congestion of the brain and its membranes, and of the lungs, and infarcts of the kidney, and of an enlarged and softened spleen. In this case only 45 grains were administered, 30 grains being given at one time and the remainder after a short interval.

Dr. Acker greets with pleasure the advent of any drug that will control the temperature in typhoid fever, and thinks he has found it in antipyrin; but he frankly admits that it does not arrest the natural evolution of the disease.

The discussion following this paper was equally significant, the weight of opinion being decidedly against the use of antipyrin in typhoid, as the personal experience of some of the members present had illustrated the very dangers pointed out by Dr. Acker.

My personal experience with these remedies is hardly relevant to the present question; for, while I have used them many times as analgesics, and without ill effects, I have only used the acetanilide in two cases of typhoid, and then with but negative effects; that is, it reduced the temperature but slightly and temporarily, while the gastric disturbance attending its use was greater than that from the remedy for which it was substituted for the purpose of relieving the stomach. But all this signifies nothing, for, as already pointed out by Dujardin-Beaumetz, the danger from acetanilide lies not in its use as an analgesic, but as an antipyretic; for the obvious reason that conditions requiring antithermic measures are invariably associated with asthenia or a tendency thereto; while, in typhoid, are superadded grave anatomical changes, which call for reparative treatment, rather than that involving further disintegration of structure and impairment of function and vital force.

These, then, are the objections to the purely antipyretic treatment of typhoid, just reviewed:

It does not shorten the course of the disease.

It only relieves symptoms of secondary importance, while adding complications sometimes of the gravest importance.

It supersedes remedies which give fair promise of aborting the disease at the outset, or failing in this, of both mitigating its severity and shortening its duration.

What are these remedies? Probably the best so far known are those already named. Each one of them is more or less commended to our confidence by clinical reports and comparative statistics which show better results than either antithermic or expectant measures; but it is the purpose of this paper to consider but one of them.

Two years ago I had the honor to propose to this Society the salicylate of ammonium as a specific germicide, antiseptic and antipyretic especially adapted to the treatment of typhoid and allied fevers, and septic inflammations; submit-

ting these provisional propositions, among others, subject to the results of further experience :

The salicylate of ammonium is to be ranked among the most efficient of the antipyretics.

In all fevers characterized by extreme adynamia it ranks among the safest, owing to its ammonium base.

It is stimulant as well as antipyretic, and thus of itself fulfils indications only met by a combination of remedies.

It is an agent of wide germicidal powers, being promptly efficient in affections of great etiological and pathological differences, each confessedly arising from its own proper specific infecting microörganism.

As a remedial agent in typhoid and remittent fevers it is unsurpassed ; aborting them at the outset under favorable conditions and greatly mitigating their severity and danger under circumstances less favorable.

These conclusions were submitted with some diffidence, not from doubt of their substantial accuracy, for they had been drawn from an experience of two years with cases differing widely in character and severity, but from regret that the new remedy had not the good fortune of a better sponsor, of well-known and respected authority.

During the two years that have elapsed since that time more than fifty cases have fallen under my personal observation, including both typhoid and remittent fevers, and that other vague class, with somewhat too indeterminate clinical boundaries—typho-malarial fever. These have afforded, under the same treatment, substantially the same results as reported in the first series of cases. Some of them were aborted in the first two or three days of high temperature, after a preceding malaise of several days ; some ran a week, and some nearly two weeks, with mild symptoms throughout. My notes show but three cases lasting beyond the tenth day, except one discharged convalescent on the tenth day but a week afterward suffering a mild relapse. This, it may be remarked, was the only case of relapse that has occurred, and this might doubtless have been averted but that the patient, who lived far in the country, thought it unnecessary to send for help.

One was a case that passed unrecognized for the first two weeks. The patient, a man of 70, found himself unable to empty the bladder, and sent for aid to the nearest physician, who resorted to the catheter twice daily for a week. At the end of this time I was sent for, and obtained a history of continuous fever and progressive decline, the urinary trouble still remaining. Cystitis was excluded by the character of the urine ; and, in the absence of abdominal symptoms, the elevated temperature seemed best accounted for by urethral fever. Quinine was given to control this, and for support, and a nourishing diet was directed. For a week more the temperature continued

to range from 101° to 102° , but vesical adequacy returned in the course of two or three days.

About this time his wife took to her bed, after several days of great lassitude, and soon afterward their son, both displaying the typical features of typhoid, including—in the case of the latter—hæmorrhage from the bowels. The former had considerable subsultus and delirium, and almost constant hiccough for twenty-four hours. But notwithstanding these untoward symptoms and her advanced age—over 70 years—her temperature fell to normal on the seventh day, and her convalescence was rapid enough to enable her to resume her duties as nurse to her husband before his fever had quite left him.

These coincident and similar cases are suggestive in several particulars. The first may be regarded as a type of the hospital case in this respect, that when its character was fully recognized it had passed beyond the point where abortive treatment was available. It is true that, as a mere antipyretic and antiseptic measure, ammonium salicylate was given in the same manner as in the associated cases, but, however, without any expectation of a like result. The remedy did all that was possible under the circumstances ; it steadily subdued the temperature and gave a degree of comfort during the course of sickness remaining not known in its first half.

The second case illustrates the practicability of abortive treatment in cases where recovery at all is problematical. The age of the patient, and the early occurrence of marked asthenia, were more suggestive of stimulating and supporting than of specific measures—in fact, were calculated to discourage the latter as more likely to uselessly perturb than benefit.

Again, a comparison of the expectant and abortive methods is here afforded, as significant as a much larger number of cases would ordinarily permit. It proves nothing, but it presents probabilities too strong to be disregarded.

Another case has interest because the typhoid attack occurred in the eighth month of pregnancy, and because of the temporary substitution of acetanilide in the treatment. This was because the salicylate was not at first well borne by the stomach. For three days the acetanilide would often reduce the temperature a degree to a degree and a half, then it rose to 103° , when the ammonium salicylate was given again, with the effect that the high temperature came down three degrees within twenty-four hours, and disappeared entirely three days afterward, when I found the patient sitting up and well enough to be discharged. Her fever had run a course of nine days.

In this case there was no doubt of the diagnosis, for the clinical history was complete, and another case occurred in the same house during her convalescence.

(To be concluded.)

FOUR CASES OF OOPHORECTOMY.

Read before the Medical Society of the District of Columbia, April 18, 1888.

BY J. TABER JOHNSON, M.D.,
OF WASHINGTON, D. C.

Case 1.—Mrs. S., æt. 33, married, the mother of two children, the youngest being 8 years old, has been a sufferer more or less since the birth of her last child; at first from subinvolution, then from prolapse, and for the last three years from an incurable anteversion, and all the time from painful and profuse menstruation.

I have been her physician for about fifteen years, and during the past seven years have exhausted all my resources to keep her uterus in position and lessen her monthly flow, without accomplishing any lasting good. During the summer of 1885, when about to leave the city for a two months' vacation, I turned her over to Dr. Magruder, who reported upon my return that he had been unable to keep her uterus in position.

The next summer I went to Europe, and Dr. Byrm attended her with a like experience. In addition to her troubles already mentioned she had hydrometra, passing at times with a sudden gush half a pint or more of muddy-looking water from the uterus. Whenever the uterus was lower down than usual she had reflex nausea and persistent vomiting, which could only be relieved by replacing the organ and retaining it in position by some artificial support.

During the last year the tenderness became so great that she was unable to wear anything but a cotton tampon. She suffered much from ovarian pains also. Several months ago I discovered a fibroid enlargement in the anterior wall of the uterus. In the three months following this discovery it doubled in size and interfered constantly with the function of the bladder. She was compelled to remain most of the time in her room, only taking dinner with the family. The general tenderness in the pelvis had increased so much by January 1, 1888, that I was at my wits' end. She could no longer tolerate the cotton supports, and she was in greater need of them than ever before.

I believed she had a growing fibroid, and that she had a stormy, painful and dismal life before her, and I saw only one way out of her troubles—unless electricity would help her. I tried this several times, but each application made her so nervous and affected her so unpleasantly that she finally refused to have any more of it. I then told her that I had but one more arrow in my quiver, and that was Tait's operation.

She thought it over and talked it over with her family and friends, and finally requested that it should be done, as she much preferred to run the risk of death than to live on in the same way she had been for the past few years, with no other prospect of relief.

She entered my private hospital on the 9th of

February last, and I removed the uterine appendages on the 11th of the same month. She made a perfect recovery, without rise of pulse or temperature. She had no pain and took no medicine.

As she had been so long an invalid, she remained in the hospital two months in order to regain her strength as much as possible before resuming her duties as head of her household. I cannot better state the result than by quoting a few lines from a letter she left for me when she departed:

MY DEAR DOCTOR:

It is not without regret that I leave your Sanitarium to-day. I am reminded of the feelings with which I came. After suffering every moment of nearly four years, until it was far easier to choose the rest which death gives than living—now to return home free from pain; can one help loving a place where she was so changed. Oh, what a change has been wrought. I go from here verily a new creature. To say you have given me back my life and health, through the blessing of God, is only telling a part. Only a few weeks since the thought of living was a burden; now the word life means volumes. Oh for the pen of a ready writer, that I might tell you of my gratitude, etc.

Case 2.—Miss S., sent me by Dr. Wells from Hyattsville, only 17 years old. She fell from a hammock three years ago and injured the end of her coccyx. Since that time has had constant coccygarlina with a desire to pass water every ten or fifteen minutes. She has led a miserable existence. Many physicians have seen her, and still she grows worse instead of better.

Last winter she went to Baltimore and spent four months in a hospital under the care of an eminent gynecologist. Added to her other troubles she had valvular disease of the heart, a legacy from frequent and painful attacks of rheumatism, and a constant burning pain in the left ovary. This finally became her most distressing symptom. She was sent to a private room in the Providence Hospital, where, after a month spent in ineffectual treatment, I removed the painful ovary and also about an inch of the injured coccyx. She made a good recovery, and has been perfectly relieved of her ovarian pain and her tormenting desire to pass water. For awhile she was free from pain in the spine, but recently has been suffering from muscular pain about the seat of injury. In this case only one ovary was removed, as the other appeared to be normal.

Case 3.—Mrs. S., æt. 37, married nineteen years ago, when only 16. Has never been pregnant; has always suffered at her monthly periods.

She came under my care about the 10th of March. She had been under medical treatment of all known and many unknown varieties for more than twenty years, and I had no hesitation in at once advising the removal of the uterine appendages. This was agreed to by the patient and her family. She came to my hospital, and the operation was done three weeks ago to-day.

Much difficulty was experienced in removing

one ovary, which was enlarged to the size of a lemon. It ruptured as it was being drawn out of the incision, and its contents, which were black and thick and sticky, were expelled into the abdominal cavity. I had much trouble to cleanse the omentum and intestines, as the water used to wash out the cavity failed to dislodge this gluey, gummy black mud it looked.

I put in a drainage-tube, but was very anxious for the first week. On the morning of the fifth day she had a temperature of 101° , by night it was nearly 106° , and the patient had that indescribable facial expression which oftens betokens speedy death when the peritoneum has been injured. I gave her 20 grs. of quinine with calomel and Rochelle salts, and put an ice-water coil over the abdomen, and when I bade her good-night I never expected to see her alive again.

In the morning her temperature had gone down to 100° and she has done perfectly well ever since; is now sitting up in a chair and walking about her room, is free from pain and I feel sure will soon be well.

Case 4.—Mrs. W., æt. 26, married, no children, was brought to me by Dr. Ralph Walshe. Mrs. W. had been well up to six months ago, when she began to suffer with constant pain in her back. Dr. Walshe found an enlarged and tender and prolapsed ovary. No treatment was of any avail—she constantly grew worse, and when any pressure was brought to bear upon the ovary she had nausea.

During the last two months it grew rapidly and, being located deep down in Douglas' pouch, there was constant pain. A strong current of electricity was tried, but the effect was unpleasant; she had to go to bed for several days, had a rapid pulse, fever and abdominal tenderness. It was not repeated.

When I saw her with Dr. W., I at once recommended its removal. This was agreed to by herself and husband and family. She entered my private hospital on the 12th inst. and I removed the tumor on the 14th. It proved to be partly ovarian and partly a broad ligament cyst, or else two small cysts and ruptured into each other.

The patient is now in her fifth day, with a pulse of 84 and temp. of 99° . Has suffered from wind colic. While she has much pain from this source, her pulse and temp. remain about normal.

MEDICAL PROGRESS.

ELECTROLYSIS IN DIAGNOSIS.—DR. E. C. GEHRUNG, of St. Louis, in speaking of the diagnostic value of electrolysis, says:

From the literature on electro-therapeutics, as well as from my own practice, I consider myself authorized to state that one of the effects of electro-puncture, especially by the cathode or negative pole, is that the tissues perforated by the non-insulated part of the electrode become matted together and form a more or less continuous fistulous tract, whereby the escape of fluids into the interstices or intervals between the different tissues so perforated is prevented. It also appears to modify the tissues along the tract of the electrodes so that inflammatory processes will rarely, if ever, be witnessed. Even punctures through the peritoneum seem to be of little importance, for which we have the attest of many trustworthy authorities.

If these premises are correct, we may conclude that:

1. Electro-puncture, especially if combined with drainage, etc., is a curative agent for many tumors, as fibroids, cysto-fibroids, cysts of a great variety, and abscesses, and that,

2. Electrolysis renders exploratory punctures comparatively harmless, and far superior to ordinary acupuncture with aspirator needles or the needles of the hypodermic syringe, which latter means have formerly been recommended to clear up a doubtful diagnosis.

Based upon these facts, we are authorized, when the absolute differentiation between two possibilities has failed, when put to the test of the usual legitimate means of diagnosis, and especially if both otherwise admit of electrolytic treatment for their cure, we are not only authorized, but may safely use the drainage-electrode to clear up the mystery. The question being decided, either electrolysis alone or combined with drainage may be used, as the case demands. In many cases, an otherwise doubtful diagnosis may thus be decided, while in fact the curative treatment for either is started. This appears to me to be a far safer way to differentiate than by opening the abdomen when in doubt.

Had Dr. Semeleder, in his operations on ovarian cysts by electrolysis, made his punctures at the most dependent portion and drained the cysts, he would very probably have lessened the duration of the treatment considerably, diminished the number of punctures necessary, and lessened the mortality in his cases. Dr. Semeleder would probably have found more followers. Dr. Apostoli advises and practices electro-cautery puncture for hydrosalpinx. Dr. A. makes a large fistulous tract by means of a large trocar. This corroborates my view as expressed above, that most intra-

A CLUB FOR THE DEAF.—It is proposed to establish in Glasgow a club for the exclusive use of the deaf, and the proposal has the support of several Glasgow aurists, since the bringing together of persons that can speak fluently, but are dull of hearing, or altogether deaf, would promote social intercourse and further the science of lip reading.

pelvic and intra-abdominal cysts can be so reached and drained, and, I feel certain, with much greater facility and safety by my trocar and cannula in combination with electrolysis.—*Amer. Jour. Obstetrics*, August, 1888.

PSYCHICAL BLINDNESS THE KEY TO A LESION IN THE ANGULAR GYRUS.—In his Address on "The Surgery of the Brain and Spinal Cord," at the fifty-sixth annual meeting of the British Medical Association, DR. WILLIAM MACEWEN related the case of a man who had received an injury about a year previously, suffered from deep melancholy, strong homicidal impulses, relieved by paroxysms of pain in the head of indefinite seat. Though the pain was excruciating he welcomed it, as it temporarily dispelled the almost irresistible impulse to kill his wife and children or other people. Prior to receiving this injury he was perfectly free from impulses of this kind, and had led a happy life with his family. Behind the angular process of the frontal there was a slight osseous depression, which could not account for his symptoms. There were no motor phenomena, but on minute inquiry it was discovered that immediately after the accident, and for about two weeks subsequently, he had suffered from psychical blindness. Physically he could see, but what he saw conveyed no impression to his mind. An object presented itself before him which he could not make out, but when this object emitted sounds of the human voice, he at once recognized it to be a man, who was one of his fellow-workers. By eyesight he could not tell how many fingers he held up when he placed his own hand before his face, though by the exercise of his volition in the act, and by other sensations he was cognizant of the number. He had been in the habit of reading the New Testament, and when he had so far recovered from his injury, he wished to resume his reading. He knew where the book lay near his bed and could put his hand on it in the dark. One day he stretched out his hand, took the book, recognizing it, through the sense of touch, by its smooth leather covers, and the deeply indented letters on its back; he opened it, saw what he considered must be the letters, and the blocking of them into divisions for the words, but they were unknown symbols to him, they conveyed no impression of their meaning, the memory of their signs was gone, it was a sealed book to him. These phenomena, however, gave the key to the hidden lesion in his brain. On operation the angular gyrus was exposed, and it was found that a portion of the internal table of the skull had been detached from the outer, and had exercised pressure on the posterior portion of supra-marginal convolution, while a corner of it had penetrated and lay imbedded in the anterior portion of the angular gyrus. The bone was removed from the brain and re-implanted in proper

position, after which he became greatly relieved in his mental state, though still excitable. He has made no further allusion to his homicidal tendencies—which previously were obtrusive—and is now at work.

Such cases of complete mind-blindness are rare, and the definite localization in this case will assist in indicating in man what function the anterior portion of the angular gyrus and the posterior portion of the supra-marginal convolution subserve.—*Brit. Med. Journ.*, Aug. 11, 1888.

GUNSHOT WOUND OF LIVER COMPLICATED WITH COMPOUND COMMINUTED FRACTURE OF THE RIBS.—DR. A. P. FRICK, Ft. Selden, N. M., reports the case of a healthy man, æt. 57, accidentally receiving a 44 calibre pistol shot wound, $5\frac{1}{2}$ inches to the right of the anterior median line of the body, and about midway between the axilla and the anterior superior spinous process of the ilium, emerging posteriorly about 1 inch lower, and $5\frac{1}{2}$ inches from the posterior median line of the body. The portions of the seventh, eighth and ninth ribs lying in the track of the ball were comminuted. Profuse hæmorrhage continued for more than twelve hours, when it ceased spontaneously. Five days later, under ether, the two wounds were connected by an incision, the loose fragments of bone removed and the sharp edges rounded off. This exposed a lacerated wound of the right lobe of the liver, with an abscess $1\frac{1}{2}$ inch deep about in the middle of the exposed portion of the liver. The lacerated parts were trimmed and the abscess opened, drained and irrigated. A drainage-tube was then inserted and the wound closed with interrupted suture, sublimate dressings applied, and the patient proceeded to a good recovery, complicated only by some troublesome bedsores and a slight necrosis of the proximal end of the ninth rib, being discharged perfectly recovered three months later.—*Phil. Med. Times*, May 1, 1888.

TREATMENT OF UNUNITED FRACTURE OF THE NECK OF THE FEMUR.—In the *Riforma Medica* of August 14 a case is related in which PROFESSOR LORETA successfully treated an ununited intracapsular fracture of the neck of the femur by scraping the fractured surfaces and inserting a bundle of metallic sutures between them. On January 23 a robust man, æt. 36, was admitted into the Bologna clinic with the history of a fall on the left hip nineteen months previously, since which he had been quite unable to stand and had suffered from constant severe pain, shooting from the left hip-joint into the gluteal region, the point of greatest intensity being over the course of the sciatic nerve. The limb was much wasted, but it was normal in position and scarcely at all shortened. Flexion and extension of the thigh on the pelvis were almost impossible, but the patient

could occasionally execute very slight movements of rotation and abduction. In rotation, he was sometimes conscious of faint crepitus in the trochanteric region. On February 15 Professor Loreta operated with full antiseptic precautions. He made a long incision behind the great trochanter, so as to expose the capsule of the joint, when he noticed a depression between the intracapsular and extracapsular portions of the neck of the femur. On moving the limb, it was found that there was a fracture without displacement in that situation. The capsule was then opened, the fibrous tissue between the fragments divided, and the fractured ends carefully freshened by scraping with a raspator. As it would have been very difficult to wire the fragments, a bundle of from eight to twelve metallic sutures was introduced between them, and brought out at the lower angle of the external wound. The wound was carefully cleansed, a drainage-tube inserted, the edges brought together with deep and superficial interrupted sutures, and the whole covered with a sublimate dressing. A long outside splint was then applied. Five days after the operation the bundle of metallic sutures was removed, and the wound healed by first intention. In less than a month the pain had permanently ceased, and fifty-five days after the operation the patient left the hospital, being able not only to stand, but to walk with no further support than an attendant's hand.—*British Medical Journal*, August 25, 1888.

OXYCYANIDE OF MERCURY THE BEST OF ANTISEPTICS.—Compared with the corrosive chloride (*Comptes rend. d. Soc. d. Biol.*, July 6, 1888, p. 585):

1. Its solution has a slightly alkaline reaction and precipitates albumin only slightly.
2. It is less irritant than solutions of sublimate.
3. There is less absorption by tissues than in case of sublimate.
4. Solution $\frac{1}{1300}$ th does not attack, except slightly, the materials used in surgical instruments.
5. Tested by its power of keeping soup, the antiseptic power showed itself six times greater than that of the bichloride.
6. Tested by the power to destroy the micrococcus pyogenes aureus, the advantage was slightly in favor of bichloride, $\frac{1}{1300}$ th to $\frac{1}{13000}$ th.
7. Employed on suppurating surfaces or to render a mucous surface antiseptic, it furnishes much better results because of the tolerance by tissues and of feeble absorption.

The cyanide of mercury has about the same properties, but the oxycyanide is more powerful against the micrococcus pyogenes aureus.—*American Journal of the Medical Sciences*, Sept., 1888.

PAPOID IN THE TREATMENT OF DIPHTHERIA.—DR. J. R. BROMWELL, of Washington, reports

six cases of diphtheria in which papoid was used successfully. From the results in this limited number of cases he feels justified in drawing the following conclusions:

That papoid, applied to diphtheritic membranes, is a safe and reliable solvent. That it possesses antiseptic properties; that the temperature falls rapidly with the disappearance of the membrane, which, according to Jacobi, proves the rapid absorption and elimination of the diphtheritic poison; that the phenomena of secondary blood-poisoning were absent, owing to the rapid solution of the membrane, supplanting the processes of suppuration by which it is removed if left to itself. That the period of incubation either varied from eight days to thirty-five days, or the poison was conveyed to the two children, who had no communication whatever with the sick, by the clothing of those who did the nursing. That age is not exempt; that there is a marked family susceptibility to the poison of diphtheria, as evidenced by the fact that, whilst a friend who assisted in nursing, and the servant, a colored woman, who was in the sick-room a dozen times a day, escaped, every member of the family, from the youngest child to the grandmother, contracted the disease.—*Amer. Journ. Obstetrics*, August, 1888.

CHLORIDE OF METHYL AS A LOCAL ANÆSTHETIC.—The cold developed by the passage of chloride of methyl from a liquid to a gaseous state was utilized some time since by a French surgeon, M. Debove, for the purpose of inducing local anæsthesia. Certain modifications have been introduced by M. BAILLY, of Chambly, by which the method has been rendered much more practical and safer. Instead of freezing the part by allowing a jet of the gas from a siphon receptacle to play upon it, he saturates plugs of cotton wool with the liquid, and places them on the spot to be operated on, or on the seat of pain. It has been found exceedingly useful in the treatment of neuralgia, sciatica, etc. To facilitate the transport of the liquid he has designed a double glass tube, the inner one containing the methyl, and the space between the two tubes being rendered a vacuum. By means of a capillary tube the anæsthesia can be directed to particular spots too small for the application of a tampon. When the latter is employed, in five or six seconds the skin becomes blanched, indurated, parchment-like and depressed. The anæsthesia thus obtained is amply sufficient to allow of incisions, scarifications, cauterizations, etc., without sensation.—*British Medical Journal*, August 4, 1888.

TREATMENT OF ABNORMAL DEVELOPMENTS OF EPIDERMIS; CALLOSITIES, CORNS AND WARTS. (ROSEN, *München Med. Wochens.*, No. 28, 1888) following Nussbaum's suggestion, has employed

salicylic acid in substance instead of dissolved in collodion, applying it as a powder upon the lesions in question, and covering with moistened bandages. The results have been very good. The method consists of the following procedure: The lesion to be treated is first made moist with an aseptic solution, and then covered with quite a thick layer of salicylic. Over this is placed some of the finest borated lint in four thicknesses, and the whole is bound down with a piece of gutta-percha. This dressing is to remain, in ordinary cases, for five days without being disturbed. After the dressing is removed the pathological process is found easily and painlessly cured, and without any bleeding. In more obstinate and harder lesions the dressing must remain on for ten days, or after five days be renewed.—*Journal of Cutaneous and Genito-Urinary Diseases*, September, 1888.

BITUMINATE OF IODOFORM.—The application of iodoform is a favorite method of treatment of chancres with many, but there are certain disadvantages attached to it which sometimes render its use impossible. These are, in the first place, the disagreeable odor, which often shuts off the patients under treatment from the society of their fellowmen; secondly, the drug is not well borne by every one, and it occasionally excites an erythema or an eczematous eruption which compels its withdrawal; and thirdly, in ulcers with overhanging edges, the use of iodoform sometimes excites such exuberant granulations that they spring up and press against the undermined edges of the ulcer, preventing the escape of pus formed beneath. DR. S. EHRLMANN writes in the *Centralblatt für die Gesamte Therapie*, for July, 1888, that he had long sought to obviate those disadvantages, and finally lighted upon a mixture of iodoform and tar, which seemed to answer the purpose admirably. After a long series of experiments, he succeeded in combining these two substances in such a way that a new preparation was formed in which the particles of iodoform and tar were so intimately mixed that under the microscope only hyaline plates were to be seen, the characteristic crystals of iodoform being not at all, or only indistinctly, recognizable. This bituminate of iodoform, as it has been called by the writer, is a substance somewhat resembling mica, consisting of translucent and transparent scales, of a brownish metallic color, which are easily pulverizable. The characteristic odor of iodoform is wholly absent, and only a slight, mildly aromatic, and not unpleasant smell of tar is perceptible. This is so faint that it is noticeable only when a large quantity of the substance is present, and even this may be covered by mixing a mere trace of liquid storax with a large quantity of the powder. When the preparation is shaken up with a large amount of water the odor

of iodoform returns, but water in small quantity does not have this effect. From this it follows that in wounds having a very profuse secretion the application might not be strictly odorless, yet the author says he has used it in a case of a very extensive bubo, and after two days there was no odor perceived by either the patient or those about him. Dr. Ehrmann has used the bituminate of iodoform with success in the treatment of soft chancres, especially phagedenic, as a dressing, after the opening of suppurating buboes, in gummy tumors and ulcers of the leg. The powdered substance is applied to the ulcer and covered with a thin layer of wadding, over which is placed the ordinary dressing. The dressing is changed every 24 to 48 hours. In the case of soft chancres which are so situated that the dressing becomes saturated with urine, or which secrete profusely, it may be necessary to renew the dressing twice daily.—*Journ. Cut. and Genito-Urinary Dis.*, Sept., 1888.

A NEW METHOD OF TREATING TORPID ULCERS.—DR. F. SPÄTH says, the principal reason for the faulty healing and want of proper cicatrix formation in torpid ulcers, depends upon the imperfect blood supply to the borders, which are usually composed of calloused connective tissue. Upon such a poorly vascularized base, only weak and flabby granulations can spring up. The same conditions prevail if the base of the ulcer is composed of a fascia. The new method of treatment proposed by Späth, consists of free division through the ulcer's borders and into the sound skin, so that the cut edges gap far apart. When the blood flow has been well stopped and an iodoform permanent dressing applied to the wound, an abundant granulation formation takes place, which very quickly leads to cicatrization of the ulcer. In such cases as this the result of cutting around the ulcer, as well as transplantation, are equally ineffectual.—*Centralblatt für Chir.*, No. 14, 1888.

NUTRIENT AND SEDATIVE ENEMA.—The *Revue de Thérapeutique* recommends the following formula:

R.	Bouillon of beef	3ij 5j.
	Eggs	j.
	Bordeaux wine	5vj gtt. xv.
	Sodium bicarbonate	gr. viij.
	Tincture of opium	gtt. iv.
	Chloride of sodium	gr. iij.
	Peptone	5iv. ℥.

ANTISEPTIC SOAP.—PROF. REVERDIN gives the following formula of an antiseptic soap that is quite soft to the hands, cleansing and disinfecting them without causing any irritation:

Sweet-almond oil	72 parts.
Soda lye	24 "
Potash lye	12 "
Sulphocarbonate of zinc	2 "
Essence of roses	9 "

SATURDAY, SEPTEMBER 29, 1888.

SECONDARY MIXED INFECTION IN TYPHOID
FEVER.

Until recently the term typhoid fever was applied to a complexus of symptoms, well recognized and defined, and accompanied by a peculiar lesion of the intestinal tract. As now understood says DR. BAYARD HOLMES, in a paper recently read before the Chicago Medical Society, typhoid fever means the invasion of a non-pyogenic microorganism, however that invasion may take place—whether by way of the intestinal or respiratory tract, and whether or not accompanied by the classical symptoms that characterize abdominal typhus. He says typhoid fever is the infection of the typhoid bacillus, and the direct consequences of such infection. There may be symptoms and results due to infection by other microorganisms, but these he regards as accidental complications, and are not parts of the typhoid disease.

He claims that when the typhoid bacillus invades the human organism, the inflammation of the lymph-glands caused by the irritation of the bacillus and its ptomaine so diminishes their resistance that secondary invasion by pathogenic and other bacteria becomes an easy matter. Some of these bacteria are normal human parasites, causing no injury to the healthy organism. But when any part of the intestine is dead, or when the equilibrium—the neutrality—between the normal organism and its bacteria is destroyed,

the usually harmless and perhaps helpful bacteria may set up a destructive colonization of the tissues, and produce suppuration, coagulation-necrosis, hæmorrhagic infarction, lymphatic engorgement, or any of the results so frequently seen in the infectious diseases.

The typhoid patient, on account of the local intestinal or laryngeal lesion, is easily infected with the pus-microbe, and all the more easily because of his general condition, due to the typhoid infection; a few days continuance of which is sufficient to interfere materially with the usual power of resistance of the lymph apparatus to bacterial invasion. A Peyer's gland, once infected and engorged, may be soon attacked by suppurative bacteria, and this second infection becomes the direct cause of the ulceration and sloughing of the tissue. He thinks the operations of the new factor are shown by the symptoms *i.e.*, the less regular remissions of the temperature, which now assumes a septic character. In favorable cases, the micrococci, carried into the mesenteric glands, he thinks may be arrested and destroyed, the glands returning to nearly the normal condition. In other cases, however, we are told that the filtering power of the overtaxed glands is overcome, and the lymph circulation is flooded with bacteria, which get into the lungs, setting up a second capillary embolism, with the presence of a parasite that can cause destructive inflammation—the pneumonia that Murchison says "rarely appears before the third or fourth week, and may terminate in small abscesses, or, rarely, in gangrene."

But according to Dr. Holmes the presence of the pus-microbe is not the only condition essential to the production of destructive inflammation, nor does it always set up the suppurative process in tissues whose vitality is so much lowered as that of the lungs in the third week of typhoid. From the investigations of De Bary and Grawitz there is reason to believe that we have not attached sufficient importance to the resistance of the tissues. Not all, if even a small part, of the bacteria are arrested in the lungs. Doubtless many of the emboli are taken up by the pulmonary lymphatics and carried to the mediastinal glands, to be destroyed; for we not infrequently see these glands enlarged, and sometimes broken down into abscesses. Sometimes, he adds, when there has been no indication of infection of the

tributary parts, the central lymph-glands become enlarged, and even undergo destructive inflammation. Dr. Holmes reports a case in which, on account of high temperature apparently due to axillary adenitis, he extirpated the enormously enlarged glands; the temperature fell to normal on the fourth day (from 103°), and the patient made an uninterrupted recovery. In this case the evening temperature was normal on the thirty-fifth day of the fever, and continued so for four days, when the patient began to eat solid food. On the forty-first day the temperature rose to 100°, and on the forty-seventh day it was 103°, when the axillary glands were removed. But there are cases in which, after a time, the balance of power ceases to be on the side of the patient, there is no resistance to the invasion of the septic coccus, and abscess formation takes place in all parts of the body. These abscesses may be very small; Popoff has shown that in the brain they are almost always miliary and multiple. And besides multiplying in definite localities, the bacteria may multiply in the circulating blood, constituting a septicæmic condition. Nor is this all. Dr. Holmes says, the destruction at the first point attacked by the pus-microbe may be so great as to involve all the coats of the intestine, and perforation may result. "In this way the largest serous cavity of the body is at once hopelessly infected, and fatal issue is not long delayed." A case of abscess of the spleen in typhoid, successfully operated on by Lauenstein, of Hamburg, was reported in *THE JOURNAL* of March 31. Even when the destructive process, of itself, does not cause speedy death, it may involve a blood-vessel, and cause death from hæmorrhage.

When the resisting power of the tissues has been reduced to a minimum by the low state of nutrition, in typhoid fever any part of the body where germs are present may become infected. Old scars open up, and old bone disease lights up again, from the germination of lasting spores. Such are the views, briefly stated, presented in Dr. Holmes' paper.

SELLING THE SAME GOODS TWICE.

It is, so far as we know, a maxim neither of political economy nor of commerce, that a person should sell the same goods twice to the same per-

son, and try to make him think he is getting something new. This is what the non-graded medical schools of this country are doing. It is not done in other countries; the United States is peculiar in being the only civilized country on the face of the Earth where there are any non-graded schools; it is the only country where a student can graduate in medicine after having had but two courses of lectures; the only country where he can be graduated without having had the advantage of *practical* in addition to theoretical courses; the only one in which the examination for graduation is not always as much or more practical than theoretical; and the only country in which there are medical colleges that admit the student without inquiring into his fitness to enter upon the study of medicine.

As we say, it is in this country alone that medical colleges exist that sell the same goods twice to the same student. This is what the two-course, non-graded schools are doing. When one reads in an annual announcement that one of the requirements for graduation is "two full courses of lectures," he need read no farther to know that the student entering in 1888-89, to take two courses, must in 1889-90 pay for what he has already had and paid for in 1888-89. Nor need one look farther to know that this school is one of a class that graduates, *in two years*, 346.9 students out of every 1000 matriculates, while there is another class that graduates but 209.6 of every 1000 *in three years*—a difference of 137.3 graduates in the 1000 matriculates.

Is it just to the student to sell him the same goods twice, and at the same time put among the "extras" courses that he must take before he is fitted for the practice of medicine? If courses in medical and physical diagnosis, operative and minor surgery, practical chemistry, practical pathology, diseases of the eye and ear, diseases of the chest and throat, operative obstetrics, and diseases of the skin, are not important parts of a medical education, why are they placed in the course at all, even as extras; if they are important why are they not always required for graduation? From one college announcement, of 1888-89, it is seen that while the aggregate fees for the tickets to all the lectures amount to \$140, the aggregate fees for "Private instruction not included in the regular curriculum or in the requirements for graduation" (9 courses) is \$182. The reader of this an-

nonnecement is supposed to believe that "The members of the senior class are instructed *practically, in connection with the recitations*, in the most important operations in midwifery and gynæcology;" but we doubt if he will believe it after a moment's thought.

It may be said that when a student attends a school that sells him the same goods twice, and tells him on graduation day that he is fully prepared to practice medicine, when he is not, he does so with his eyes open. Very true; we make most of our mistakes in life with our eyes open. But it is possible that while his eyes may be open, the student does not see—as he will before he has been in practice six months—and it is more than probable he will not recognize the injustice done him. The second-course student will inform the first-course student at his side that Prof. B. will tell a certain story to-day, and that next Tuesday he will tell another. What is that second-course student doing by the side of the first-course man? He is buying the same goods twice. Others have done it before him, and he thinks it is proper. He will see his mistake when it is too late—after he begins practice. We classify studies in primary schools, in grammar schools, and in colleges; why make a heterogeneous pill-mass of medical study, and expect the student to digest it and thrive on it?

"NON-ALCOHOLIC" TONICS AND BITTERS.

DR. B. F. DAVENPORT, Chemist to the State Board of Health of Massachusetts, has recently analyzed 47 tonics and bitters. Of these 46 were found to contain from 6 to 47.5 per cent. of alcohol, the average percentage of alcohol in the 46 being 21.5 per cent. Viewed in the light of the analyses, the statements in the advertisements of some of these preparations seem somewhat misleading. One of the tonics, advertised as "not a rum drink," contains 13.2 per cent. of alcohol. Another, admitted to contain Marsala wine, contains as much alcohol as that wine. A Coca Beef Tonic, advertised as made "with sherry," contains 23.2 per cent. of alcohol, while sherry contains but 18 or 20 per cent. Parker's Tonic, claimed to be a purely vegetable extract, "stimulus to the body without intoxicating," contains 41.6 per cent. of alcohol. Whisky and brandy contain but 50 per cent. of alcohol. The advertisement of this tonic says: "Inebriates struggling

to reform will find its tonic and sustaining influence on the nervous system a great help to their efforts."

Seaweed contains alcohol according to the analysis of Schenck's Sea-Weed Tonic, which is said to be distilled from seaweed, perfectly harmless, and free from the injurious influences of corn and rye whisky. It contains 19.5 per cent. alcohol. Baker's Stomach Bitters contains 42.6 per cent. Hooiland's German Bitters, advertised to be purely vegetable, and free from alcoholic stimulant, contains 25.6 per cent. Hostetter's Stomach Bitters contains 44.3 per cent. Kaufmann's Sulphur Bitters contains no sulphur, is advertised to contain no alcohol, but contains 20.5 per cent. "Dr." Richardson's Concentrated Sherry Wine Bitters, to be taken in doses of a tablespoonful to half a wineglassful or more three times a day, or "when there is a sensation of weakness or uneasiness of the stomach," contains 47.5 per cent.—2.5 less than whisky and brandy. Walker's Vinegar Bitters, claimed to contain no alcohol, contains 6.1 per cent. Copp's White Mountain Bitters, "not an alcoholic beverage," contains 6 per cent. of alcohol. Beer and ale contain from 3 to 5 per cent. of alcohol.

When a person takes the usual "dose" of one of these mixtures—about a wineglassful three times a day, he takes the equivalent in alcohol of about half the quantity of whisky, and on an average a little more than the same quantity of sherry. Moreover, he must take his alcohol "blindfold;" it may be a good article, but the probabilities are that it is not. There are a great many people that would on no account drink beer, wine, whisky or brandy as such, but yet use these "tonics" and "bitters" freely and regularly, give them to their children, and recommend them to persons addicted to the use of alcoholic liquors, as a harmless substitute and cure for the alcohol habit, as a stimulant to flagging or a sedative to over-active organs, and as cures for the most dissimilar diseases.

Nothing better illustrates the human fondness for the mysterious than the readiness with which people buy and consume secret compounds. And while we admit as readily as any one the individual rights of the people, something should be done to prevent avaricious men from poisoning people by selling them compounds that are injurious to health.

A MISTAKE.

Some of the subscribers to *THE JOURNAL* always pay promptly each year, others generally delay until they receive a bill from this office indicating their indebtedness; and there are always a few on our books who, notwithstanding the receipt of one or two bills each year, still allow their accounts to run two or even three years, until their individual indebtedness amounts to \$10 or \$15. During the present month, it being near the end of the first quarter of the *JOURNAL* year, we authorized the clerk to send out bills as usual to all such as had not paid for the current year, simply indicating the amount of their indebtedness. For the few whose amounts had remained unpaid two or more years a special note was prepared which, after stating the amount of their indebtedness, directly requested them to remit the amount without further delay, or else notify us to discontinue *THE JOURNAL*. By some lack of attention on the part of the clerk, some of these *special notes* have been filled out and sent to subscribers whose accounts were in arrears only for the present current year, and, as might have been expected, they have been regarded as unnecessarily captious or offensive. We regret the mistake, as no such use of the special dunning letter was intended by us.

PROGRESS OF YELLOW FEVER.

The fever epidemic in Jacksonville continues. The whole number of cases reported to date, September 25, is 1991, and 217 deaths. A few new cases are reported at McClenny and some other towns in Florida. Seventeen cases and 4 deaths have been reported in Decatur, Alabama; and 14 cases and 5 deaths in Jackson, Mississippi. These indications of the spread of the disease westward in the direction of the Mississippi, has greatly increased the excitement among the people of the South and Southwest, and added much to the efforts at maintaining rigid inland quarantines, some of which appear to be judicious and well directed by the Health Boards and the Superintendent of the Marine Hospital Service, while others are injudicious and wholly unnecessary.

DR. F. SIEBENMANN has qualified as Privat-Dozent of Otiatry in Basle, and DR. AARON as Privat-Dozent in Laryngology.

EDITORIAL NOTES.

DR. GAFFKY, of Berlin, has been appointed Professor of Hygiene in Giessen.

LAUSANNE, it is thought, will soon have a complete University, as the funds have been guaranteed.

LIEBERMEISTER, of Tübingen, Riegel, of Gies- sen, and Quincke, of Kiel, have been proposed for the chair of special pathology and therapeutics in the University of Bonn, made vacant by the death of Professor Rühle.

HEADACHE FROM INTRANASAL DISEASE. — JOAL reports two cases that confirm the opinion of Mackenzie, of Baltimore, that one of the factors in the production of nasal disease is excitation of the sexual apparatus. In the *Revue Mensuelle de Laryngologie*, of July, 1888, Joal discusses some of the headaches that occur about the time of puberty. Hack claims that these headaches are due to intranasal disturbance, and his opinion is well supported.

DRAINAGE IN PUERPERAL PERITONITIS. — WOODWARD reports (in the *Boston Medical and Surgical Journal*, of July 12) a case of puerperal peritonitis that he saw about six weeks after labor. There was an extensive accumulation of pus in the abdomen, an abscess that had been circumscribed having burst into the abdominal cavity about 36 hours before labor. Laparotomy was performed, offensive pus evacuated, the cavity irrigated with hydronaphthol, 1-100, and a drainage tube and antiseptic dressing applied. The cavity was repeatedly irrigated with boiled water. The patient recovered.

CASATI'S MODIFICATION OF ALEXANDER'S OPERATION consists in making a single transverse incision through the skin, somewhat curved, with its concavity upward, thus uniting the two external rings. The round ligaments are then drawn out and shortened by excision of the redundant portions. The proximal end of each cord is then stitched to the distal end of the opposite one, thus forming a cross, which is united to the subjacent cellular tissue by a continuous catgut suture. The outer wound is closed with silk. The uterus is supported by vaginal tampons. This modification seems to be unnecessary, and the making of a comparatively complicated operation out of a very simple one.

SOCIETY PROCEEDINGS.

American Surgical Association.

Annual Meeting, held in the Main Hall, Grand Army Building, Washington, D. C., September 18, 19, 20, 1888.

TUESDAY, FIRST DAY—MORNING SESSION.

The Association was called to order at 10 A.M., by the President, DR. D. HAYES AGNEW, of Philadelphia.

The first business was the delivery of the President's Address. (See page 453.)

DR. JOHN ASHBURST, JR., then read a paper entitled

A CONTRIBUTION TO THE STUDY OF EXCISIONS OF THE LARGE JOINTS.

The following is an abstract:

The remarks which follow are based upon the records of 120 cases in my own practice, in which excisions of the larger joints have been required, and will refer particularly to the operative method, the after-treatment, and the functional value and limitation of applicability of excision in the case of each articulation. The 120 cases embrace 4 of shoulder-joint, 19 of elbow-joint, 40 of hip-joint, 51 of knee-joint and 6 of ankle-joint excision.

Shoulder-joint.—My four shoulder-joint excisions have all terminated successfully. They all occurred in adults, three times in young persons, and once in an old person. The only case of special interest was that of a young married woman, æt. 30, admitted to the hospital in a very prostrate condition, with acute necrosis of the left humerus and consequent pyarthrosis of the corresponding shoulder-joint. The upper half of the humerus was removed at the first operation, and twenty-four days afterwards the entire remaining portion of the bone, including the condyle, the only osseous tissue left being a thin shell of small extent which adhered to the periosteal sheath on the inner surface. The patient recovered rapidly, and acquired a surprising amount of use of the affected limb, and the increasing firmness showed that at least partial reproduction of bone was occurring. With the elbow supported the patient could use her wrist and hand with considerable freedom.

In excising the shoulder-joint, or, more strictly speaking, the head of the humerus, for the glenoid cavity rarely requires more than superficial scraping or gouging, I have employed the method by a single longitudinal incision. I have endeavored to avoid wounding the tendon of the long head of the biceps, but when the parts are matted together by long-standing inflammation, the tendon is difficult to recognize and is often not seen until it has been severed.

In the after-treatment I attach much importance to the use of the well-known cushion devised by Prof. Stromeyer. It keeps the elbow out from the trunk, thus insuring the close application of the sawn humeral shaft to the glenoid cavity, and enables the patient to sit up or lie down at pleasure, without disturbing the dressings.

The functional utility of the limb after excision of the shoulder-joint is, upon the whole, quite good. The operation, although seldom called for in civil practice, should be adopted without hesitation in suitable cases, such as those of suppurative arthritis, caries and necrosis, in which the indication for the operation is found either in the pain or in the exhaustion from profuse purulent discharge. For plastic or rheumatoid arthritis or for simple ankylosis, the operation is not to be recommended, for the mobility of the shoulder compensates measurably for the stiffness of the joint, and the gain which would be obtained by operation is not sufficient to justify the risk.

Elbow-joint.—Of the 19 cases of excision of the elbow-joint six have terminated fatally. Two adults died within five days from traumatic gangrene following injuries so severe that amputation would have been the better operation; one died of delirium tremens; two from tubercular meningitis; and one, an old man, from exhaustion in the course of the fifth week.

In excising the elbow-joint, I employ a longitudinal incision on the inner side of the articulation, taking care not to wound the ulnar nerve and to retain the attachment of the biceps. As a rule, all the articulating surfaces should be removed, and, within reasonable limits, the more bone that is taken away the better, since flail-like union is less to be dreaded than ankylosis.

For the after-treatment I employ a somewhat obtuse-angled, internal splint (Physick's splint), well padded and protected by oiled silk. As bony union is to be avoided, it is not necessary to use a splint to render the part immovable. As soon as the external wound has become solid the splint should be abandoned and the arm kept in a sling.

The functional result of a successful excision of the elbow is more nearly perfect than that of excision of any other articulation. Cases which justify the operation are those of destructive or gelatinous arthritis, caries, necrosis, compound dislocation or fracture not so severe as to require amputation, and even simple ankylosis.

Hip-joint.—I have forty times resorted to excision of the hip-joint in 37 patients. Twice have I excised, at intervals, both hip-joints in the same individual, and once have I had recourse to re-excision in a case in which recurrent caries and recontraction followed some months after the patient left the hospital. This case terminated fatally from suppurative osteomyelitis and septic peritonitis at the end of a fortnight. Both cases of double excision did well. Of the 40 operations

28 have been followed by recovery, 11 by death, and one is still under treatment. Of the 37 patients 25 have recovered and 11 died. Should the patient now under observation die, the mortality rate will be, as regards operations, 30 per cent.; as regards individual patients, 32.4 per cent.; a better showing than the results given by most statistical writers.

The incision employed begins with a straight cut in the direction of the fibres of the gluteal muscle, curves around and behind the trochanter and terminates again in a straight cut corresponding to the axes of the femur. While affording free exposure to the joint, it necessitates but little transverse division of muscular fibres. The head of the bone may be made to protrude and removed with the chain saw, or under other circumstances divided by a small saw *in situ*. It is my custom to remove both trochanters and round off the sawn end of the femur.

In the after-treatment I keep the limb well adducted with simple weight extension, with lateral support by sand bags. As soon as the external wound has become solid and the patient can control the motions of the limb, he may be allowed to get about on crutches.

The functional result of hip-joint excision must be somewhat differently judged from that of excision in the case of other articulations. In most instances the operation is performed only when death seems threatened by profuse suppuration or its consequences, and if the patient is relieved of pain and restored to a fair state of health and comfort, the treatment is amply justified. At the Children's Hospital, in Philadelphia, where 20 of the 40 operations were performed, the rule is not to operate except in otherwise hopeless cases and hence our recoveries represent so many lives saved, but in many cases excision not only saves life but restores the patient to the active duties of existence. In 13 of the 28 cases the patient obtained a useful limb, and in two of these the utility is qualified as perfect. The condition which most often calls for this operation is "hip-disease." I consider the operation suitable in certain cases of gun-shot injury. For uncomplicated ankylosis it is not to be recommended, simple osteotomy being here a safer and surer method. Where ankylosis co-exists with extensive caries or necrosis, excision may properly be resorted to. I am afraid that the "age limit" for hip-joint excision must still be maintained; in the case of the knee, I have ventured to extend the benefits of this conservative procedure to adults and even to middle-aged persons, and with great success; but excision of the hip-joint becomes an operation of great and rapidly increasing gravity when once puberty is passed. Thus while I count twenty-five successes and only four deaths in persons under 15 years of age, I have had only three recoveries and no less than seven deaths, in those older. In adults the

operation should only be undertaken with a clear understanding of the very great risks by which, under the circumstances, it is attended.

Knee-joint.—I have performed 51 excisions, in 50 patients, once having employed a re-excision for ankylosis with recurrent deformity, in a case in which I had excised the joint nine years before. Once I amputated the thigh ten weeks after excision, on account of beginning failure of health, and a good recovery followed. Of the 51 cases, but 5 have ended fatally, a death-rate of less than 10 per cent.

In excising the knee-joint, I have uniformly adopted the single transverse incision and have invariably removed the patella. The bone sections are commonly made with a butcher's or bow saw. I take particular care to remove all of the diseased synovial membrane, as well as all particles of carious bone. In treating the large bursa beneath the quadriceps muscle, I have endeavored to hasten the cure by making a long incision in the outer side of the limb and either dissecting the bursa out bodily, or scraping away its lining membrane with a sharp curette. If foci of softened and carious bone are found beyond the points at which it is safe to use the saw, I remove them with the gouge, and if necessary cut a channel through the osseous wall in such a way that the part may heal firmly without leaving a sinus.

In the after-treatment I employ a bracketed wire splint, which while firmly fixing both thigh and leg, enables the limb to be dressed as often as is needful without causing the patient pain. I have left the limb on the splint as long as six or seven weeks. After bony union is well advanced and the external wound is almost healed, I substitute a simple posterior splint or gutter of pasteboard. I think it important to use means of mechanical support for at least six months, particularly with children.

The utility of the limb after successful excision of the knee is very great. The limb is stiff and slightly shortened; the foot is sometimes a little inverted, but the limb is strong, painless and enduring, and enables the patient to lead an active, useful life. As a substitute for amputation, and it is as such that I employ it, the merits of knee-joint excision cannot be gainsaid.

The cases in which excision of the knee-joint is indicated are chiefly those of arthritis, particularly of the variety for which years ago I suggested the name gelatinous; of caries; of neglected epiphysitis, etc. The operation may properly be performed in ankylosis with deformity, and also in certain instances of wound of the articulation where the extent of the injury is limited. In most traumatic cases, however, I believe that where any operation is called for, amputation will be found preferable.

Ankle-joint.—I have resorted to this operation six times, although about as often I have removed

the astragalus without interference with the tibia and fibula. Two of the six cases proved fatal from phthisis, one four months and the other nine months after operation. My impression is that this operation in itself is attended with very little risk.

In excising the ankle-joint I make an external incision curving around behind and below the outer malleolus and carried forward as far as can be done without endangering the extensor tendons, and prolonged upward as far as needful in the line of the fibula. A second smaller incision is made longitudinally over the lower end of the tibia. It is usually desirable to remove the whole astragalus. This is perhaps the most tedious and difficult of all excisions, and the operation may be facilitated by rendering the part bloodless by the use of the Esmarch apparatus. The ankle-joint is the only joint, with the exception of the wrist, in the excision of which the use of this apparatus seems to me to be desirable.

Some years ago I devised a bracketed splint for the after-treatment of ankle-joint excisions. This answers a good purpose. If antiseptic dressings are used, however, the part usually requires so little disturbance that a simple posterior gutter of pasteboard, supplemented by a fracture box, will be sufficient. The foot should be kept at right angles with the leg.

The cases which seem to me to call for ankle-joint excision are those of compound fracture and dislocation, less severe than to require amputation, and those of localized caries and arthritis, in which there is no suspicion of general tuberculous infection.

The large majority of my excisions have been performed without any of the so-called "antiseptic precautions," and the wounds have been dressed with simple oiled lint or with lint saturated with dilute alcohol. For more than a year past, however, I have employed the antiseptic method in almost all my large operations, using also antiseptic dressings in their after-treatment, and I think with benefit; though I am obliged to say that as regards the ultimate welfare of the patients, I have not noticed any gain. My best series of consecutive successes have been obtained under old methods, and I have not obtained any diminution of mortality by the adoption of the new. At the same time, I have seen no ill results which could be attributed to the use of antiseptic measures; their use shortens the period of convalescence, and they have the merit, on account of the infrequent change of dressings needed, that they greatly lessen the surgeon's labor. I know of no cases which require more personal and unremitting attention than those of excision, and it is an unquestionable advantage to be obliged to dress a wound only once a week, or every other week, instead of daily or every other day.

What will be the future of the operation of articular excision? The brightest triumph of con-

servative surgery in the hands of Fergusson and his successors,—will it keep its place? or, as some of our more enthusiastic brothers prophesy, will improved methods of dealing with joint disease in its early stages, make excision a matter only of surgical history and of antiquarian investigation? It seems to me that as the introduction of excision did not enable surgeons to abandon amputation for articular lesions, so improve treatment as we may, and educate the public as we may as to the necessity of being treated early, there will always remain a class of cases in which only by sacrificing a part, can we hope to save the whole, and in which excisions of the larger joints will therefore still be resorted to by judicious and conservative practitioners.

DR. LEWIS A. SAYRE, of New York: The paper of Dr. Ashhurst has so thoroughly covered the ground that very little is left to discuss. In excision of the hip-joint I have been in the habit of using the wire cuirass for the reason that it permits the carrying of the patient into the open air, an object not readily attained when the patient is kept in bed with the ordinary apparatus. In regard to the antiseptic treatment which I practice entirely, I think that I may claim that I have used it, without knowing it, from the time that I commenced practice of surgery. I think that my success has been largely due to the practice of pouring into the wound Peruvian balsam, which, from the creasote it contains, is an excellent antiseptic. I have also always arranged for thorough drainage. When I practiced my first excision in 1854, the operation was universally condemned. Some seem to now be going to the other extreme and performing excision of the hip-joint too early, before a thorough trial of local and general treatment has been employed.

DR. R. A. KINLOCH, of Charleston: There is now no disagreement so far as the general question of excision is concerned, but there are still some important questions to be considered. In the first place, the distinction of traumatic from pathological cases amenable to operative procedure; and in the next place, as regards the joints which are apt to do best in connection with excision for traumatic and pathological processes. A consideration of the age and surroundings of the patients is of importance. Probably the best results follow excision in connection with shoulder-joint cases for traumatism. In connection with gelatinous inflammations of the elbow-joint I have had satisfactory results even where all the material could not be removed.

I feel sure that if a few of the principles of so-called antiseptic treatment—cleanliness, thorough drainage and absolute rest, are adopted, many of the details may be omitted.

DR. T. F. PREWITT, of St. Louis, insisted on the necessity of getting cases of excision in broken down children out of doors as soon as possible.

DR. F. S. DENNIS, New York, called attention to cases of excision of knee-joint for disease beginning in abscess in the condyle. In these cases the abscess cavity breaks down after recovery, leading to the production of deformity. In these cases he takes away all of the abscess cavity, saws away a corresponding piece from the tibia, and brings the oblique surfaces together.

He has been in the habit of employing antiseptic dressings, removing the drainage-tube on the third day, allowing the first dressing to remain five or six weeks. In excision for injury only enough bone to allow of free drainage should be removed.

SIR WILLIAM MACCORMAC, London: He had heard with some surprise that the tendency seemed to be to postpone excision of hip-joint until all other measures had failed. This is not the position in regard to any other joint. In England the disposition is to perform the operation at an earlier period. Another point that he had not heard mentioned in the paper was in reference to the performance of operation in cases of old dislocation of the joint. He had performed this operation with success in old hip-joint dislocation, and reported the case of a sailor coming under observation three years after the occurrence of dislocation of hip-joint which had not been reduced. After the operation he could use the limb perfectly. He had been much interested in the recommendation of Dr. Ashhurst that a long incision be made to reach the subcutaneous bursa, a suggestion which he had not heard mentioned by any other surgeon.

DR. E. M. MOORE, Rochester, had been somewhat surprised to hear a certain amount of indifference expressed towards the use of antiseptic surgery. He had found in his practice the greatest improvement follow the use of antiseptic dressing in these cases of excision. He cited several cases showing the result obtained.

DR. JOHN E. OWENS, Chicago: He agreed as to the value of the wire cuirass, and referred to a modification of this apparatus consisting in the substitution of a frame of gas-pipe conforming to the outline of the body. On this the body is supported by means of flannel stretched between the two sides of the frame. Extension may be applied, if desired, by the use of adhesive plaster, counter-extension being provided for by elevating the foot of the frame. After keeping the patients in bed for thirty days, he tries to get them into the open air. He had found great advantage in keeping up a certain amount of extension after the patient was allowed to get up. By removing pain this enables the patient to move the joint more freely, and thus tends to favor greater mobility of the part. He thought that there was no comparison between the antiseptic methods and those formerly employed.

DR. FRED. LANGE, New York, referred to a class of cases in which the disease of the hip began

in the tissue outside of the joint, the articulation becoming involved at a later stage of the affection. In these cases he recommended early operation, with the hope that in this way necessity for opening the joint would be avoided.

(To be concluded.)

Obstetrical Society of Philadelphia.

Stated Meeting Thursday, September 6, 1888.

J. C. DACOSTA, M.D., IN THE CHAIR.

DR. W.M. GOODELL read a paper entitled

A YEAR'S WORK IN OÖPHORECTOMY.

During the year 1887 he had had nineteen cases with one death; but including ten cases he had since had, there was only one fatal result in twenty-nine cases. The cause of death in this fatal case was uræmic coma from suppression of urine. How far the administration of ether was to be blamed for this renal complication he was not prepared to say, but he was inclined to think that chloroform was not so liable to cause congestion of the kidneys. The operation was performed for diseased ovaries and tubes, which were greatly crippling her.

The eighteen successful cases were performed for the following reasons and with the following results: Uterine fibroids, cured, 5, improved, 1; menorrhagia and ovaralgia, cured, 2, improved, 1; ovaralgia, cured, 3, improved, 1; epilepsy, improved, 1; hysteroneurosis, cured, 1; insanity, unimproved, 2; pseudo-muscular hypertrophy, unimproved, 1.

In his experience the removal of the ovaries for uterine fibroids is almost always followed by a cure, that is to say menstruation ceases, the tumor rapidly lessens in size and no further inconvenience results from bulk pressure.

Of the three cases of menorrhagia associated with ovaralgia, the lack of complete success in one was due to the fact that only one ovary could be removed. The other ovary was so matted in organized exudation as not to be distinguishable.

The failure in one of the cases of ovaralgia was due to the persistence of menstruation after a thorough extirpation of both ovaries. This is a very rare result, but it will occasionally happen. Menstruation usually ceases in these cases after the lapse of a few months.

In the case in which the ovaries were removed for epilepsy, the result has not, thus far, been a cure, but the attacks come at longer intervals. Hardly time enough has elapsed for the woman to reap the full benefit of the operation, for she still has regular catamenial moulimina accompanied by bloody expectoration.

Time enough has not yet elapsed to decide whether the two insane patients will be improved

or be cured by the operation. Each one was an invalid and each one became physically well, but not mentally so. In Dr. Goodell's experience, which has not been a small one, those cases which exhibit aberration of intellect only during the menstrual periods, will almost always be cured by the removal of the ovaries. But cases of insanity in which the hallucination are continuous, yet much exaggerated at the catamenial periods, are by no means so likely to be cured by the operation, although they are generally very much improved. In any case about two years time must elapse before the nerve perturbations of this artificial change of life wholly disappear, and a cure should not be expected before that lapse of time. What is true in mental cases and in purely nervous ones, is also true in a measure where even coarse lesions of the ovary are found. Hence the surgeon must not look for full results, or for complete freedom from groin aches and pelvic pains, directly after the removal of even diseased ovaries and tubes. He must wait patiently for the ovarian nismus or habit to cease, until in fact the menopause has been wholly and fully established in every way.

In the foregoing nineteen cases, the spray was not used, but every other antiseptic detail was carefully carried out. The pedicle was tied with silk; the wound was closed by the same material, and dressed with gauze dipt in a glycerole of carbolic acid. Drainage was employed but once and that in the fatal case, but this had nothing to do with the issue. Eleven of the cases were treated at his private infirmary, seven at the Hospital of the University of Pennsylvania, and one at the patient's own home.

DR. H. A. KELLY liked the moderate tone of the paper just read. He believed that here, as in other fields of work, that we must be often satisfied with relative results. He liked the term "Ovaralgia" now better than he once did. Until we are better able to differentiate the exact nature of the lesion in some of these cases, he thought the term "ovarialgia" used generically is a good one.

He had a rare case of salaam convulsion, which had been treated for a long time. He had been called in to decide the advisability of an operation, and had refused to remove the ovaries. Two years later the ovaries had been removed and the patient cured. There did not seem to be any distinct connection between the pelvic and general condition.

DR. M. PRICE asked Dr. Goodell if in these operations he had ever noticed on ligation any change in the number of the "heart beats." He had several patients, in whom, on the evening of the day of operation he had found the pulse as low as 48. He had noticed somewhere that an operator found a drop of the pulse from 80 to 35 on ligating the ovarian nerve. Since then he had

had the pulse beats counted on a number of patients at the time of the ligation, and had found a drop of only 4 or five beats at most.

DR. J. PRICE said that Dr. Johnston, of Danville, Ky., had dwelt on the matter of slowing of the pulse very fully. He thought that the explanation of continued pain after an operation was to be found in the adhesions of the intestines, etc. Some of his most satisfactory results had been obtained in cases of extensive adhesions. In a recently reported case the patient had complained of agonizing abdominal pain. An adherent omentum and a knuckle of intestine had been separated, and complete relief obtained. He had operated on a number of cases where the only lesion found was a general adhesion of the whole mass of intestines. He had thoroughly separated them and had obtained most satisfactory results. Mr. Tait has repeatedly reoperated to free adhesions. He felt that operation for nervous disturbances was of very doubtful benefit, and he never operated unless he found actual disease. He preferred handing the patient over to others.

DR. M. PRICE related a case in which the whole trouble was due to adhesions. It was supposed to be a case of gall-stones. No disease and no gall-stones were found, but the intestines were matted together, the adhesions were released, and no pain was felt afterwards.

DR. JOSEPH HOFFMAN: Dr. Price has referred to the lowering of the heart-beat after application of the ligature. In a case of his own the pulse, which on the day of operation, before ether had been given was 120, had gone down in a few hours after the operation to 58; after ten days it crept up to 80. This low register of 56 to 58 was sustained even in spite of the temperature being 101° and 102°.

DR. B. C. HIRST had operated on a case in which a small portion of one ovary was left. The case had ceased menstruating even in spite of the part left behind. A stitch had passed through the remaining piece.

DR. W. S. STEWART wanted to know the effect of removal of both ovaries on menstruation. If at the time it should occur, there were any evidences, such as acceleration of the pulse, etc., as seen at the menopause.

DR. WM. GOODELL had referred to the point suggested by Dr. Stewart in his paper, and he said that just such symptoms appeared in these cases as appeared after the natural menopause. The full results were not obtained until after these ceased. He had never noticed a fall in the pulse beats as referred to, but he had often seen serious collapse follow the pinching of the ovary. He had seen the pulse fall to 97°, and in one case below this. He thought that a counterfeited aneurism was by no means an infrequent symptom of ovarian disease. He had had a patient from a

distance suffering from ovarian enlargement, aortic pulsations, and other nervous disturbances, for which he prescribed. Afterward a local surgeon insisted that she had aneurism. A second examination convinced him that such was not the case. This was afterwards made evident by her passing through an exceedingly difficult confinement safely. There are two conditions in which he was willing to operate for the removal of the ovaries although he found no disease. One is *epilepsy*, the other is *insanity*, for in these cases a woman should never conceive. He believed that the State should interfere to prevent men and women who suffer from epilepsy or insanity from getting married. Indeed he is not sure that the day may not come when by act of legislature an insane man will be castrated and an insane woman will have her ovaries removed. He has had a good deal of experience with removal of the ovaries for insanity and has had some happy results, on the other hand, he had been disappointed at times. In cases of epilepsy he had not had so much experience. He wished that gentlemen who have had such cases would report them.

DR. C. M. WILSON had had three cases such as spoken of by Dr. Goodell. In two the result was negative. One patient was apparently benefited for some months, but recent reports say there is a gradual relapse into the former condition.

DR. H. A. KELLY had, about three years ago, operated on a girl with a brachial paresis, resulting from infantile palsy, with, also, epileptic attacks, pre- and post-menstrual in character. For some months there was no improvement but lately she has become better. Dr. Kerlin had remarked to him that if in a good many of these cases of hopeless idiots operation were performed removing their respective organs during the period of active growth, they would not develop some of their worst features and would be more easily managed.

DR. J. M. BALDY had a case, which at the time of operation looked like true epilepsy. There was excessive pain, vaginismus, and other symptoms. The pain was relieved, but not the vaginismus, for which a subsequent operation was performed. The epileptic attacks had continued. They were, however, becoming much less frequent than formerly. Some two years had now elapsed.

DR. J. PRICE operated on a patient with double pyosalpinx and epilepsy at the menstrual period and at no other time. The recovery was complete and the relief absolute. Some months after she went to another institute complaining of pain and was again opened. He wished to know whether or not in these cases convulsions come on during the period in which the patient is in bed after the operation.

DR. JOSEPH HOFFMAN had a case of three months' standing, which suffered from hæmato-salpinx and suppurating appendix. The patient

had been having epileptic attacks. She had been entirely free from them since the operation.

DR. W. S. STEWART said that he did not think that the ovaries should be removed in all cases of epilepsy, as suggested by Dr. Goodell. He had an epileptic patient whom he had confined several times and whose children showed nothing wrong about the intellectual development. He had removed the ovaries of a woman suffering from epileptic seizures and she had received no benefit from the operation. She is now in an insane asylum.

DR. GOODELL said that there was no disease so likely to be inherited as epilepsy and insanity. If Dr. Stewart lived long enough he would find the children referred to develop the disease.

(To be concluded.)

FOREIGN CORRESPONDENCE.

LETTER FROM VIENNA.

(FROM OUR OWN CORRESPONDENT.)

Use of Gray Oil in Syphilis—Tuberculosis of the Iris—Use and Application of Hyoscin—A New Austrian Pharmacopœia.

At a recent meeting of the Imperial Royal Society of Physicians of Vienna, Prof. v. Lang read an important paper on "The Use of Gray Oil in Syphilis." It was known that the metallic mercury, such as was contained in the gray salve and the gray plaster, had a very powerful influence on syphilitic affections. As, however, the subcutaneous injection of mercurial preparations had undeniable advantages over any other method, owing to its commodity and on account of the fact that it permitted an exact dosage of the quantity of mercury to be used, the author had endeavored to find out a preparation which contained the mercury in the same form as in the gray salve, and which could at the same time be used for subcutaneous injections. After repeated trials, Prof. v. Lang arrived at the following formula:

Hydrargyri	aa 3 parts.
Lanolin	4 "
Oil of olives	

The preparation under consideration contained 30 per cent. of metallic mercury, and from 0.1 to 0.15 cubic centimetres of this oil were, in general, injected during an interval of from five to eight days. After the lapse of some weeks, the injections were discontinued for some weeks, and so on, until about from 1.5 to 2 ccm. of the gray oil were used. Prof. Lang stated that he had obtained excellent results with the injections of the gray oil. The good effect of this way of anti-syphilitic treatment especially became manifested in the case of syphilis of the nervous system, where the symptoms subsided in a proportionately

short time. There were no bad after-effects. When the technique of the injection was exactly observed, and the gray oil prepared in a convenient way, one could be sure that the reaction after the injections would be but very slight. The author and his assistants had but very seldom observed the presence of stomatitis. He had used the preparation in question for the last four years, and had to discontinue this treatment for only five times. The advantages in the use of the gray oil consisted, first, in the fact that only a small quantity of mercury had to be injected; secondly, in the possibility of an exact dosage, which was not the case in the use of the gray salve.

The indications for the use of the gray oil were quite the same as those for any mercurial treatment. The mercurial oil also admitted of a larger local application than the gray plaster; it could very advantageously be applied to gummatous cavities of the bones, and also to syphilitic processes in the nose, the pharynx, the ears, the larynx and the eyes.

Professor Fuchs showed a rare case of tuberculosis of the iris. The patient was a girl 6½ years old, and many of the family were the subjects of tuberculosis. The patient herself had successively suffered from measles, small-pox and scarlet fever; an inflammation of the eye of a tuberculous character occurred after the latter. The patient was well developed, and no abnormality could be proven to be present in the lungs. The cornea of the right eye was dim, and precipitates could be discovered at its posterior surface. The pupil protruded much outward, and its internal side was for the greatest part covered by a tumor which reached as far as the cornea. The tumor itself was composed of numerous small nodules of a gray-red color. This form of the tuberculosis was very rare and, in the strictest sense, it could neither be reckoned to the disseminated or the conglomerated tubercles of the iris. In the first one there were in the iris many disseminated and isolated nodules of a gray color, whereas in the second form the tubercle had the appearance of a neoplasm in which the composition of nodules could only be recognized by means of a loop. The case under consideration was to be looked upon as primary tuberculosis of the iris. The lecturer suggested that enucleation of the affected eye would protect the rest of the organism against infection.

Drs. S. Krauss and Fischer, of Budapest, gave in a recent number of the *Orvosi Hetilap* (a Hungarian medical journal), some interesting details on the therapeutic value of hyoscin, and tried to clear up some divergent opinions which are existing in this respect.

Sohr, Kobert and Köhlwetter, as well as other investigators, had used hyoscin in doses of from 1 to 2 milligrams without observing any dangerous complication; it was only Erb who had ob-

served symptoms of intoxication in doses of from $\frac{1}{16}$ to $\frac{3}{16}$ parts of a milligram. As to the dangerous after-effects of this drug, and with reference to the divergent opinions which existed in this direction, Dr. Krauss explained them by the suggestion that the experimenters had availed themselves of different preparations of the drug in question. Hitherto, the hydrobromide, the hydroiodide and the hydrochlorate of hyoscin were used; at the recommendation of Köhlwetter, the hydrochlorate of hyoscin ("hyoscinum hydrochloricum") was used in the "Landes-Irrenanstalt" of Budapest, and the drug was directly ordered from Merck. A 2 per cent. solution of "hyoscinum hydrochloricum" was used for subcutaneous injections in the beginning, half a Pravaz syringeful, hence the dose of 0.001 gram was used. Later on, 0.001 gram was injected in the morning and the evening. The injections (altogether 90 in number) did not cause any greater pain than other drugs, and they were not refused by the patient. No bad after-effect could be discovered, neither was any serious complication observed, though the drug was used for decrepit patients. The hyoscin was applied in all irritative conditions, viz.: in acute maniacal and hallucinatory irritations, in post-epileptic attacks of frenzy, and severe paralytic irritation. There was no opportunity for ascertaining the value of the drug in the case of paroxysms in delirium of the drunkard ("delirium potatorum") and melancholia, neither in the excessive irritability of the so-called "raptus melancholicus."

From the experiments hitherto performed it became already evident that the hydrochlorate of hyoscin excelled all the other respective remedies hitherto used, owing to its excellent sedative and hypnotizing effect. Its sedative effect invariably manifested itself, and in the acute maniacal irritative conditions its influence was even quite surprising. The patient who just before was in a condition of the highest hyperkinesis became quite paralyzed after one injection, and after the lapse of from six to ten minutes, or at the latest after fifteen minutes, the muscles entirely lost their function, and this condition, which bore a resemblance to the state of deep drunkenness, lasted for about twenty minutes, when the patient fell into a sleep of the duration of about from two to four hours. After awaking the patient remained quiet (tranquil) for about six hours. In the case of paralytics the effect was not so striking. The individuals attacked with mania broke down after the injection, as if they were thunderstruck, whereas the paralytics became only gradually more quiet, and in some cases they became affected with an amnemoniacal humor. It had still to be mentioned that the hyoscin was used in such irritated patients in which the usual drugs, such as chloral, morphia, paraldehyde, either had no effect at all or only a little influence. Also in

patients suffering from agrypnia, and where the hypnotics, except paraldehyde, were not attended with any success, the hyoscin, in the dose of 0.001 gram, produced undisturbed sleep of from five to six hours' duration, though it at the same time gave origin to a little degree of giddiness and nausea. Paraldehyde was very ill supported by the patients, owing to its disagreeable taste and smell; moreover, it was very dear, and did not permit of an extensive application.

Appearances of intoxication did not occur one single time; circulation and respiration remained normal. Vomiting occurred once. The authors could not share in the opinion pronounced by Kühlwetter, viz.: that hyoscin could be administered only to robust individuals, as they had prescribed it to anæmic and emaciated patients without any harm. It was administered ten times to patients who, for several years, had suffered from tabes and progressive paralysis.

Hyoscin had no influence on the temperature, and the eye-pupils, in most of cases, did not undergo any change.

From all the observations now referred to it became evident that the excellent effect of hyoscin was beyond any doubt, and that it could not be compared with any of the sedatives hitherto known. The influence of chloral hydrate, as was known, was uncertain, and especially failed to manifest itself in the case of much irritated paralytics, and, on the other hand, its dosage could not be exactly determined. On one occasion 2 grams were not sufficient, and on another occasion this dosage was too large and attended with symptoms of intoxication. Moreover, it was known that in chronic psychoses which were combined with permanent irritation, the chloral hydrate was attended with several disagreeable after-effects, the least of which was that the patient became accustomed to the drug and that the dose had to be increased. Again, the use of morphia in psychical diseases was limited to only very few affections, and in most of the psychoses it was nearly without any effect, and properly exerted an influence only in the case of paroxysms of fear in melancholia. The value of the paraldehyde became impaired by its bad taste and smell, as well as by its high price. Hence, so far as we could judge from our present experience, the hyoscin had to play a great part in the therapy of the psychical diseases.

Its sure, rapid and complete effect rendered it superior to all other similar drugs; moreover, it was cheap, if we took into account the minimum doses which were required. Further experiments might detect some inconvenience, but in any case, the drug under consideration was worth being fully studied not only by the specialists, but also by the general practitioners.

The committee for the edition of the new "Pharmacopœia Austriaca" have completed their

work; the new Pharmacopœia will appear in the course of this year and become compulsory in the beginning of next year.

DOMESTIC CORRESPONDENCE.

LETTER FROM NEW YORK.

(FROM OUR OWN CORRESPONDENT.)

The College of Physicians and Surgeons of New York; the New Buildings; Changes in the Curriculum and Length of the Term—Death of Dr. Thomas T. Sabine—The Late Dr. Henry F. Quackenbos—Method of Dealing with Small-Pox—The Chimpanzee Called "Mr. Crowley," of Central Park—Fatal Dose of Chlorate of Potassium—The Visit of Professor von Eschsch, of Kiel.

The College of Physicians and Surgeons, the next session of which commences October 1, announces with satisfaction that the new group of buildings, given by the late Wm. H. Vanderbilt and his family and by Wm. D. Sloane, Esq., have amply fulfilled the high expectations formed of them as centres for improvement in medical teaching. For the session of 1888-89 and thereafter, it will be remembered, a preliminary examination is to be required of all new applicants for matriculation, with the exception of those who possess diplomas from recognized colleges or schools of science, or who can present satisfactory evidence of proficiency in the various subjects requisite for admission to the institution. With a view to elevating the standard of medical education, the Trustees and Faculty have also resolved upon important changes in the length of the session, the amount and character of the obligatory studies, the requirements for graduation, and the fees for instruction.

Beginning with the present season, the college year is henceforth to consist of a period of vacation, extending from Commencement to about the first of October, and of an annual session of between eight and nine months, extending from the latter time to the following Commencement, which will be held on or about the 15th of June. At the same time the absolute number of required didactic lectures is not to be increased; so that a greater number of hours each week will be available for other exercises. The work of all students who are candidates for the degree of M.D. will be distributed over three years of study, according to a prescribed curriculum, and as regards the requirements it is announced that candidates who are not already graduates in medicine of recognized institutions must have pursued the regular three years' curriculum at this college, or the regular curriculum of the second and third years, and such a course at some other medical school as shall have been recognized by the Faculty as an equivalent for the first year's curriculum. Graduates in

medicine of recognized institutions must have pursued at this college at least the regular curriculum of the third year, and all candidates, whether already graduates in medicine or not, must pass a satisfactory final examination in writing, which, in addition to the seven regular branches, will include "clinical studies." The examination in the topic of "clinical studies" is to comprise one question in each of the following subjects, set by the clinical professors thereof: Diseases of the mind and nervous system; diseases of the genito-urinary organs, including syphilis; diseases of children; diseases of the eye; diseases of the ear; diseases of the throat; diseases of the skin. With the exception, however, of such graduates in medicine as attend only the third year of the curriculum, candidates, if they so elect, are eligible for examination in any or all of the three branches, anatomy, physiology and physics and chemistry (and upon them only), on completing the first two years of the curriculum.

The necessary expenses for graduation, for a student who attends the curriculum during three years, are as follows: First year.—Matriculation, \$5; fee for all the required exercises of the year, \$150; anatomical material, \$1 each part.

Second year.—Matriculation, \$5; fee for the required exercises of the year, \$150; anatomical material, \$1 each part.

Third year.—Matriculation, \$5; fee for all the required exercises of the year, \$150; graduation fee, \$30.

The college has just met with a severe loss in the death of Dr. Thomas T. Sabine, who has been Professor of Anatomy since 1879, and who was a popular teacher, a skilful surgeon, and a most accomplished and genial gentleman.

The career of the late Dr. Henry F. Quackenbos, who recently died at his home in this city at the age of 69, was in many respects a notable one. Like his father, who was also a physician, he was born in New York, and both were graduates of Columbia College. He received the degree of M.D. from the College of Physicians and Surgeons in 1840, and soon afterwards went abroad, pursuing the study of his profession in London, Edinburgh and Paris. While residing in Paris he was appointed surgeon of a brigade commanded by Gen. Pellissier, afterward Duke of Malakoff, and served in the French campaign in Northern Africa against the Algerians. Returning to his native city in 1849, he distinguished himself by his heroic services while in charge of Bellevue Hospital during the cholera epidemic of that year. Dr. Quackenbos soon acquired a large private practice in New York, and his *clientèle* was made up to a considerable extent of members of the theatrical profession. He was honorary physician of the New York Dramatic Fund Association from its organization, and for many years he was the medical adviser and intimate associate of Edwin For-

rest; who, it is said, if taken ill while travelling through the country, would always send for Dr. Quackenbos to attend him, however great the distance might be.

In referring to the remarkably small number of cases of small-pox occurring in New York of late, although the disease has been more or less prevalent in some of the neighboring cities and towns, Mr. Bayles, President of the Board of Health, recently made the following statement: "I believe the reason for the singular exemption of New York to be almost wholly due to the system of isolation now in use, which is wonderfully expeditious. The moment a case is reported by the physician in attendance the inspector in whose district the case occurs is at once sent to look it up, and if he has any doubts about the character of the disease he sends immediately to the central office, when one of the expert diagnosticians is dispatched to his assistance. All the district inspectors are in telephone communication with the central office, so that no time is lost; and the period that elapses between the report of the case and the removal of the patient to the hospital is frequently not more than four hours." If, as is usually the case, the patient cannot be properly isolated at his own home, he is sent at once to the reception hospital on the East River, preparatory to removal to North Brother Island, on which are now located the hospitals for contagious diseases. The bedding and other effects are removed to the disinfecting house of the Health Department, and the disinfecting corps thoroughly fumigate the entire premises. Of course, the vaccination of those exposed to the risk of contagion is also carefully looked after.

"Mr. Crowley," the intelligent chimpanzee whose wonderfully human-like actions have for several years been the admiration of the crowds visiting the zoological department of Central Park, died about the first of September. He was presented to the Park in June, 1884, by Mr. Smyth, the American Minister to Liberia, who purchased him when at an early age from a Congo negress, who is said to have suckled him at her own breast. On his arrival in New York he was only twenty inches in height, and could be readily carried in a great-coat pocket. At the time of his death he was four feet nine inches in height. Not long before this his weight amounted to 110 pounds, but illness reduced this finally to 73 pounds. A most admirable portrait of him has been made by Mr. Frank Beard, the well-known animal painter. The picture represents the chimpanzee seated in an arm-chair beside a table, with one hand holding a copy of Darwin's "Descent of Man," and the other supporting his head, while the attitude and the countenance are indicative of the most profound meditation. Two skulls are in the foreground, and the picture bears the inscription, "Strange, isn't it?"

During the four years that Crowley was at the Park menagerie he had several severe attacks of pneumonia, and the greatest possible care was always taken of him, both in sickness and health. The autopsy was made the day after his death by Dr. William Gotheil, who found the animal very badly diseased. The left lung was practically useless, and was firmly bound down by old adhesions, while there were evidences of pleurisy in the right lung, and the immediate cause of death was ascribed to congestion of that organ. Abundant tubercular deposits were found in many parts of the body, notably the liver, and there was marked fatty degeneration of the heart. There were also evidences of an old peritonitis, and the lymphatic glands were in a state of chronic enlargement. The brain, which is to be thoroughly examined by Dr. E. C. Spitzka, was entirely healthy in its gross appearances, and weighed about one-third of that of the average adult human brain. The convolutions representing the functions of speech were four in number—considerably less than in the human subject.

Both the skeleton and the stuffed skin of the dead chimpanzee are to be mounted and placed on exhibition in the admirable collection of the American Museum of Botanical History, on the west side of the Park. A new section of this institution, which will ultimately be of immense size, is now in course of erection; the legislature having last year appropriated the sum of \$400 for the purpose. In the new building there will be a handsome lecture-room, with a seating capacity of 1500. During the past year a number of important additions have been made to the Museum, including the Lawrence collection of American birds, numbering 12,000 specimens; a collection of 4000 Brazilian birds, and the Elliot ornithological library, of over 1000 volumes.

A death has been reported here from chlorate of potassium, two half ounce doses having been taken in mistake for iodide of potassium.

Among the recent arrivals in this city are the eminent surgeon, Professor von Esmarch, of Kiel, and his wife, the Princess Henrietta of Schleswig-Holstein, who is a near relative of the present Empress of Germany. They are accompanied by their son, Dr. Ervin von Esmarch. They were met down the Bay by a number of friends, and escorted to the residence of Dr. Frederick Lange; and a few days afterward a reception was tendered the distinguished party at Terrace Garden. At this entertainment the Princess presented 1200 marks for distribution among the Schleswig-Holstein poor resident in New York. P. B. P.

MEDICAL EDUCATION OF THE LAITY.—*The New York Medical Journal* in a recent editorial on this subject says: What the laity need is not to be more thoroughly instructed in medical science, but to be taught to distinguish between the true and the false, between the charlatan and the honest conscientious physician.

Reply to the Criticism of Dr. Robert Newman.

Dear Sir:—Dr. Newman says:

1st. "Is it sound logic to condemn an operation and method because a *novice* (italics mine) has made a failure in a few cases, when surgeons of undoubted standing from all parts of the world have reported hundreds of successful cases?" etc.

I treated six cases in succession by electrolysis, and not one was benefited. After such a fair trial was I justified in wasting the time and patience of my patients any further? Treating a patient two months without improvement does not add greatly to one's reputation. Have not surgeons of still more undoubted standing from all parts of the world condemned the treatment? Need I repeat their names to Dr. Newman?

2d. "Why was not the cystitis treated first?"

It would be as logical to treat an acute inflammation of the eye caused by a foreign body and then remove the foreign body, as to try and cure the cystitis first and then remove the strictures. The cystitis was a *result* of the strictures.

3d. "Had the gentleman carefully read my papers he would not have made his paper a personal attack."

I deny the personal attack statement. I simply used the name of Dr. Newman (also one other) as being the exponent of a method that I had found by experience, although at first prejudiced in its favor, to be of no value. My experience conforms also to the experience of the first genito-urinary surgeons in Dr. Newman's own city. My paper was written from a purely scientific standpoint. Persons with a hobby are apt to be very sensitive.

4th. "I . . . do not enlarge the urethra to a certain theoretical size, but mark in my statements "cured," when the patient feels and is well, passes a free, unobstructed stream, and is satisfied with his condition to such a degree that he objects to any further treatment and enlargement, and does not desire a larger-sized urethra."

I do not claim that a patient should have his urethra enlarged to a "certain theoretical size;" every patient his own individual standard as can be demonstrated with the urethrometer, but "when the patient feels well, passes a free unobstructed stream, and is satisfied with his condition." I do not by any means concede that he is cured. I make that concession only when the bulbous bougie or urethrometer fails to discover a stricture. As long as a *stricture* still remains there is the exciting cause for a gleet or cystitis. Dr. Newman apparently leaves the patient to be the judge as to when a cure is effected.

5th. "It is easier to enter the urethra with the tapering instrument than with a six-sizes larger egg-shaped bulb."

"Goodness Gracions!" and the doctor even

diagrams it for fear his readers could not comprehend so wonderful a problem. Some of us use steel sounds that are not tapering, so that the extended argument about tapering instruments is all wasted.

6th. "The next mistake Dr. Thomas makes, is in saying that some patients were discharged with their urethras admitting only a No. 14 French."

And then Dr. Newman, in the same breath, admits that one improved very slowly to No. 14 and something prevented his return. If I had more leisure time I would hunt up the record of the other case, but as the doctor drops one-half of his *casus* it is hardly worth my while to hunt up the other half.

7th. "Dr. Thomas does not state in his report of the single case, how he used the electrolysis, nor does he tell what his most approved apparatus was."

The battery I used was a McIntosh galvanic. My electrode bougies were those made by Truax & Co., and are identical, I believe, with those used by Dr. Newman. The electrode (negative) two sizes larger than the stricture was placed against the face of the stricture, the current turned on, beginning with one cell, and gradually adding cell by cell until the current was quite perceptible to the patient, and at the same time making steady but gentle pressure. Before removing the electrode the current was gradually diminished; séance lasting from fifteen to twenty minutes.

8th. "Candidly I do not envy any one who can use such language, and I leave it to my readers to surmise what animus has prompted him."

Any one reading my previous article can see at once that I was honest and after the truth—even an enthusiast. The "animus" requires no "surmise;" it is plain.

To show to what extremes some reporters may go, Mr. Editor, please permit me to give you this excerpt from a journal lying before: "Mr. H. M., merchant, æt. 28, has had stricture of the meatus and gleet for two years. This case was very slow in consequence of the *very great contraction* (Italics mine), and subacute inflammation setting in from the slightest manipulation. I finally disregarded the inflammatory condition, and with a flexible conical electrode bougie, No. 24 French, and 18 cells of a Stammers' battery, worked through, and thoroughly broke down the stricture. Quite a high grade of inflammation was set up, which soon subsided, leaving the meatus free from all contraction. . . . He has remained well up to this time (four years). This case illustrates the fact that electrolysis will substitute internal incision, even at the meatus."

Very great contraction means one of filiform calibre. To work through a stricture of this

kind with a No. 24 bougie at one sitting is almost incredulous, and under conditions when electrolysis is entirely contraindicated by the teachings of Dr. Newman. Did the electrode go through by causing absorption, or did it burn through, or did it go through *volens volens*?

J. D. THOMAS, M.D.

Pittsburg, Sept. 12, 1888.

MISCELLANEOUS.

MEDICAL SOCIETY OF VIRGINIA.—The Nineteenth Annual Session of the Medical Society of Virginia, will convene at 8 P.M., Tuesday, October 23, 1888, in Norfolk, Va. Dr. Herbert M. Nash, of Norfolk, Va., will deliver the *Address of Welcome*. Dr. Wm. T. Walker, of Lynchburg, Va., will deliver the *Annual Address to the Public and Profession*. Subject, "Moses and other Doctors." Dr. Benjamin Blackford, of Lynchburg, Va., will deliver the *President's Address*. Subject, "The Progress of Medical Education, and the Importance of the Study of the Physical Sciences in relation thereto during School Life."

The Society will nominate to the Governor of Virginia for appointment, as members of the Medical Examining Board of Virginia, for the term of four years, beginning January 1, 1889, thirty-two regular practitioners of medicine in Virginia, as follows: Two from the State at large, and three from each of the ten Congressional Districts of the State.

The night session will begin about 7:30 o'clock with the call for reports on advances in the several departments of the medical sciences. The following order will be observed until adjournment to Thursday morning when the call will be continued until this order is completed—no paper to exceed thirty minutes in reading:

Advances in Anatomy and Physiology.

Advances in Chemistry, Pharmacy, Materia Medica and Therapeutics.—In this Section the following paper will be presented: "The Carbon Compounds—Their True Place in the Treatment of Fevers; or the Particular Forms of Fever in which They are Indicated," Dr. S. K. Jackson, of Norfolk, Va.

Advances in Obstetrics and Diseases of Women and Children.—In this Section the following paper will be presented: "Conduct of Eeeneinte Women before and after Confinement," Dr. Wm. L. Robinson, of Danville, Virginia.

Advances in Practice of Medicine.—In this Section the following papers will be presented: "The Uric Acid Diathesis," Dr. J. Spotswood Wellford, of Richmond, Va. "The Development of Medicine," Dr. M. A. Rust, of Richmond, Va. "The Duty of the Doctor to his Patient Suffering under Malignant Disease," Dr. William W. Parker, of Richmond, Va. "Thirty-two Years' Experience as a Country Practitioner," Dr. Charles R. Cullen, of Richmond, Va.

Advances in Surgery.—In this Section the following papers will be presented: "Exploration of the Bladder for Obscure Diseases of that Viscus," Dr. Hunter McGuire, of Richmond Va.—By invited guest, Dr. Milton Josiah Roberts, of New York, N. Y.

Advances in Ophthalmology, Otolaryngology and Laryngology.—In this Section the following paper will be presented: "Enlarged Tonsils—What Shall We do With Them?" Dr. Charles M. Shields, of Richmond, Va. "Improved Means of Diagnosis in Throat and Nasal Troubles, with Remarks on Treatment," Dr. Joseph A. White, of Richmond, Va.

Advances in Hygiene and Public Health.

Advances in Psychology and Neurology.

In addition to the above reports, by resolution adopted at the last annual session, Drs. Wm. W. Parker, of Richmond, Va., Dr. Wm. P. McGuire, of Winchester, Va., and

T. M. Bowyer, of Liberty, Va., were appointed a Committee to "Report a Record of All Deaths Known to have Occurred during the Past Five Years in this State from the Administration of Chloroform."

When this order shall have been completed, call will next be made for voluntary scientific papers, contributions and reports—titles of which have not been received in time to be assigned to any special department. All papers should be ready for immediate delivery to the Recording Secretary at the time of their presentation to the Society.

Dr. Landon B. Edwards will propose the following amendment to Section 1, Article I, of the Constitution of the Society, relating to eligibility to Fellowship, etc.: After the word "surgery"—the last word of the Section—insert, "or who has not received, in due form, the certificate of having passed a satisfactory examination before the Medical Examining Board of Virginia."

The Profession of Norfolk and Portsmouth have arranged for suitable entertainment of their guests which will be named during the session of the Society. Dr. Alex. Tunstall, Norfolk, Va., is the Chairman of the Local Committee of Arrangements for this session.

Fraternal delegates from any of the recognized regular medical societies of the country will be recognized upon presentation of their certificates of appointment as such, and will enjoy all the privileges of the Session allowed to non-resident Honorary Fellows and invited guests. It is desired that they shall participate in the scientific proceedings of the session, either by reading papers or entering into the discussions upon papers read, cases reported, etc.

PROF. DIEHL read the report on "The Progress of Pharmacy," at the Third-sixth Annual Meeting of the American Pharmaceutical Association. The following excerpt will be of interest to the profession:

"It is clearly the duty of the pharmacists to attend to the preparation, dispensing, and sale of medicine, in which event he must, or should, conform to the code of ethics of the medical profession. The renewal of prescriptions is an evil for which the physician is equally responsible. The sale of patent medicines, while it can not be avoided, need not be encouraged by the pharmacist. The physician, on the contrary, should not whimsically designate the products of special manufacturers in his prescription, and he certainly should not supply the medicines needed in his prescription if such can be filled in the locality in which he resides. The professions of medicine and pharmacy are so intimately related that they can not afford to quarrel."

The *National Druggist*, commenting on the report, says: The discussion of the report was animated and earnest and was generally participated in, especial attention being given to the points touching upon the differences between pharmacists and physicians. The opinion seemed to be general that these differences were more apparent than real, and that all that was needed to heal the breach was a closer communion with and a better understanding of each other.

DR. S. D. MCINTOSH, the well-known electrician of Chicago, has been invited by Dr. Charles N. Hewitt, President of the American Public Health Association, to attend the next meeting of the Association to be held in Milwaukee, Wis., Nov. 20, 21, 22, 1888, so that members may avail themselves of his personal services in the use of the stereopticon with sunlight or oxy-hydrogen light, for the illustration of papers or addresses. Members wishing such illustration should communicate with Dr. Hewitt, Red Wing, Dak.

THE KIRK SESSION of the Glasgow Cathedral have divided the collection, made on the occasion of the recent meeting of the British Medical Association, between the Dumoon and Lenzie Convalescent Homes.

LIST OF PERMANENT MEMBERS.—The name of Dr. I. M. Harsh, of Griswold, Ia., was unintentionally omitted from the published list.

THE NEW MILITARY HOSPITAL at Alexandria, Egypt, contains 137 beds and is built on the site of the old Light-house Fort.

THE ILLUSTRATED MEDICAL NEWS is the title of a new weekly medical journal. It is published in London and the initial number appears to-day.

Official List of Changes in the Stations and Duties of Officers Serving in the Medical Department U. S. Army, from September 15, 1888, to September 21, 1888.

By direction of the President, the Army Retiring Board at San Francisco, Cal., convened by War Department order dated July 20, 1886, published in S. O. No. 168, July 22, 1886, from Headquarters of the Army, is dissolved. Par. 1, S. O. 217, A. G. O., September 18, 1888.

By direction of the acting Secretary of War, the leave of absence granted Major Alfred A. Woodhull, Surgeon, in S. O. 148, June 27, 1888, from this office, is extended fifteen days. Par. 14, S. O. 218, A. G. O., September 19, 1888.

By direction of the acting Secretary of War, Capt. Robert J. Gibson, Asst. Surgeon, is relieved from duty at Alcatraz Island, Cal., and will report in person to the President of the Army Medical Examining Board, New York City, on October 16, 1888, for examination for promotion. On completion of his examination Capt. Gibson will proceed to Ft. Trumbull, Conn., and report for duty to the commanding officer of that post, reporting by letter to the commanding General Div. of the Atlantic. Par. 13, S. O. 217, A. G. O., September 18, 1888.

By direction of the acting Secretary of War, First Lieut. Edward R. Morris, Asst. Surgeon, is relieved from duty at Ft. Thomas, Ariz., and will report in person to the commanding officer, Ft. Shaw, Mont., for duty at that post, reporting by letter to the commanding General Dept. of Dak. Par. 14, S. O. 217, A. G. O., September 18, 1888.

Official List of Changes in the Medical Corps of the U. S. Navy for the Two Weeks Ending September 22, 1888.

Asst. Surgeon George A. Lung, ordered to receiving ship "Vermont," Navy Yard, New York.

P. A. Surgeon A. G. Cabell, ordered to the Naval Hospital, Chelsea, Mass.

P. A. Surgeon J. W. Baker, detached from the Naval Hospital, Chelsea, Mass., and to the "Palos."

P. B. Surgeon Philip Leach, detached from the "Palos" and granted six months' leave abroad.

Surgeon M. A. Simons, detached from Naval Academy and wait orders.

Surgeon G. E. H. Harmon, ordered in charge Naval Academy.

Asst. Surgeon Geo. McC. Pickrell, detached from "New Hampshire" and to the "Ossipee."

Asst. Surgeon W. F. Arnold, ordered to the "New Hampshire."

Asst. Surgeon C. P. Henry, detached from the "Ossipee" and granted sick leave.

Asst. Surgeon F. J. B. Cordeiro, promoted to P. A. Surgeon.

Medical Inspectors J. C. Spear and A. C. Rhoades, placed on the retired list September 14.

CORRIGENDUM.

In the issue of September 22, p. 429, appears a communication on "The Ethics of Marriage." The signature should read Hunter H. Powell, instead of "Rowell."

ORIGINAL ARTICLES.

SHOULD NOT THE NATIONAL GOVERNMENT DEFEND OUR PORTS AGAINST THE NATIONAL ENEMY, CONTAGIOUS DISEASE?

Read in the Section on State Medicine, at the Thirty-ninth Annual Meeting of the American Medical Association, May, 1888.

BENJAMIN LEE, A.M., M.D., Ph.D.,

OF PHILADELPHIA, PA. SECRETARY OF THE STATE BOARD OF HEALTH OF PENNSYLVANIA.

To ask this question ought to be to answer it. To one who views it from the broad standpoint of a humanitarian nationalism it would seem that there can be but one response, and that an affirmative one.

The only argument which has been adduced against it is, that the power of enforcing quarantine is a police power, and as such, reserved by the constitution to the several sovereign States. I confess myself, unable to find any such reservation. On the contrary, Section 8 of Article 1, of that immortal document, declares that "Congress shall have power to provide" not only "for the common defence" but for the "general welfare of the United States," "to regulate commerce with foreign nations," and "to make all laws which shall be necessary and proper for carrying into execution the foregoing powers, and all other powers vested by this constitution in the government of the United States or in any department or officer thereof." More than this, the several States are expressly forbidden to "enter into any agreement or compact with a foreign power." Now, I am quite willing to grant that the enemies against which a "common defence" is thus guaranteed, are the armies and navies of foreign nations and not bacilli or cryptogams, although in a more highly advanced state of civilization a liberal interpretation might even include these latter more formidable foes; but I ask:

First. What possible interest is there which more nearly concerns "the general welfare" than the protection of the entire nation from the introduction of pestilence from abroad?

Secondly. How is it possible to administer quarantine relations without, to a greater or less extent, often to a very serious extent, interfering

with the "commerce with foreign nations," from which the States are expressly bidden to keep hands off? and

Thirdly. In what way can such a reciprocal understanding be arrived at between the government of any State, still less of any City, and foreign governments, as the rapidity and immensity of modern intercommunication makes absolutely essential if the transportation of contagions is to be brought under control, when the said State and municipal governments are forbidden in so many words "to enter into any agreement or compact with a foreign power?"

Internal hygiene, the making of all laws which shall promote health, protect life, and prevent the transportation of contagion within the limits of each State, this certainly is a right reserved to each State by exclusion; but when it comes to the question of common defence against a common enemy from without, which more persistently and terribly than any other, threatens the "general welfare," an appeal to the constitution appears, both by analogy and by literal construction, by the letter as well as by the spirit, to lead to but one conclusion, viz., that this latter power inheres in the general government.

This question has, however, been practically decided by Congress, in placing a fund at the disposal of the President, to be used at his discretion in taking measures to prevent the introduction of contagious diseases in especial emergencies, in assigning to a subordinate Bureau of the Treasury Department the duty of establishing quarantine stations at certain points under certain conditions, and of requiring the consular representatives of the nation to report the progress of contagious diseases in foreign countries to that Bureau.

We may, therefore, consider that objection as finally tabled, and proceed to discuss the question whether the National Government, *having the right* to assume control in this matter, is not *in duty bound* to exercise it. In considering this subject I shall not scruple to avail myself of the admirable work already done, contained in the following papers, viz: "Practical Recommendations for the Exclusion and Prevention of Asiatic Cholera," an address delivered by Dr. John H. Rauch, Secretary Illinois State Board of Health,

before the National Conference of State Boards of Health at St. Louis in October, 1884; "Coast Defences against Asiatic Cholera," a report of an Inspection of the Atlantic and Gulf Quarantines between the St. Lawrence and the Rio Grande by the same author; "Report of the Committee of the College of Physicians of Philadelphia, appointed to investigate the efficiency of our Quarantine arrangements for the exclusion of Cholera and epidemic diseases," an Editorial Article from the *Medical News*, of Philadelphia, Nov. 5, 1887; An Address from a Special Committee of the College of Physicians of Philadelphia to the Medical Societies of the United States, concerning the dangers to which the country is exposed by the ineffectual methods of Quarantine at its Ports, and in regard to the necessity of National Control of Maritime Quarantine; and a "Report of the Committee on Epidemic Diseases" of the Senate of the United States.

If it should be found on investigation that, under the system which leaves the management of quarantine to local authorities, whether State or civic, every quarantine station without exception has been generously supplied with everything necessary in the way of extensive grounds, so situated as to make isolation easy and complete; of commodious buildings for the reception, detention and observation of suspects, and well-arranged and ample hospitals for the treatment of the sick; of establishments and apparatus for the complete and rapid disinfection of both effects and vessels; we might conclude, simply from a sanitarian standpoint, that federal interference was uncalled for. If, on the other hand, we find that, except possibly in a single instance, not one of these conditions has been discovered to exist, we are forced to the conclusion that neglect of this duty on the part of the government is longer inexcusable; and if, moreover, we find that in the mature opinion of some of the ablest sanitarians and physicians in the country, it is impossible from the very nature of things that these favorable conditions could invariably be presented under State and local management, such neglect becomes a folly and a crime. In reference to this last point, Dr. Rauch says:

"With two or three exceptions, no port in the United States has adequate facilities for the proper administration of quarantine. Such a system as was inaugurated by the National Board of Health, and which is the only quarantine contemplated in these remarks, involves the removal of an infected or suspected vessel out of the track of commerce; the segregation of her sick from the well; the proper care and shelter of both these classes; the necessary disinfection of infected cargo, and the purification of the vessel; and the release of vessel, cargo and persons, so soon as they have been rendered safe and free from the danger communicating disease.

"This is very different from a mere quarantine of detention. It is the American quarantine of sanitation, a common sense quarantine, which aims to prevent the introduction and extension of contagion, not by merely arresting it at a given point and there leaving sick and well at its mercy until, the susceptible material having become exhausted, no more cases of the given disease occur; but by removing the susceptible at once from its influence, and then destroying it and the conditions necessary for its existence by scientific methods of disinfection and purification.

"To do this, however, requires a quarantine plant and facilities far beyond the means of any but the largest ports, supported either by abundant quarantine fees or by adequate appropriations from the State or municipality. But cholera may obtain access at a small port as well as a large one, and hence the necessity for the Refuge Stations above indicated."

And later in the same address, "Sooner or later the National Government will be compelled not only to assume supervision of exterior quarantines, but to provide for a permanent system of coöperation with State and local governments in the administration of inter-State sanitation; in order, on the one hand, to prevent the introduction of exotic epidemic diseases, and, on the other hand, to prevent their spread from State to State along the great international highways of travel and commerce. *This is a National duty.* It is one that the *National Government only* can adequately discharge, and its expense is, equitably, one which should be defrayed *from the National Treasury.*"

The report of Dr. Rauch's tour of inspection is already a classic. It goes without saying that, while he found much to commend in the devoted and painstaking attention of individual officers to quarantine duties, he discovered, with very few exceptions, an almost entire absence of all the essentials of a thoroughly equipped quarantine station. Commenting upon this he says:

"During all this time, from the earliest date to the present, the control of quarantine has remained entirely under the jurisdiction of State and local authorities, except during the brief period in which the National Board of Health exercised its limited quarantine powers under the act of 1878, and which expired in 1882. It is this absence of adequate National health authority and legislation, and the fact that, in such absence, the maritime quarantines are controlled and administered by State and local authorities—resulting in diverse, and frequently conflicting, regulations and requirements and, of necessity, in a tendency to limit precautions to their own individual interests, commercial as well as sanitary—which throw upon interior States the responsibility of fully informing themselves of the strength or weakness of these outposts, in order to know where to an-

ticipate danger and how to make their own preparations to meet it.

"At its last session, Congress appointed a Commission to examine and report upon the measures necessary for the defense of our seacoast against a foreign armed enemy, and a distinguished publicist and statesman, Mr. Tilden, has recently urged this as a paramount duty of the Government. Millions of dollars have already been expended for such defense, and millions more will probably be forthcoming to meet this possible contingency. But the assaults of foreign contagion are not a contingency. They are actual events, and during the past twenty years they have cost the country an aggregate loss of life only less than that of the great war immediately preceding. Every sanitarian and many of our leading statesmen know that this actual and ever-recurring loss is wholly and entirely preventable by the expenditure of a sum which sinks into utter insignificance before the millions which will be appropriated for the protection of our coasts against a possible future danger.

"But thus far neither sanitarian nor statesman has been able to overcome the petty jealousies of individuals, communities, and of States themselves, so as to secure the legislation necessary to remedy even the present confusion."

Early last autumn two or more cholera-infected ships lay in New York Harbor, while the disease was spreading with considerable rapidity among the passengers who had been disembarked upon Hoffman's Island for observation. Impressed with the gravity of the situation, the College of Physicians of Philadelphia, one of the most venerable and least aggressive of American medical societies, on the 5th of October, appointed a committee "to consider the present danger of the importation of cholera into this country, and to secure concerted action among the medical societies of the land in urging upon the State and National authorities the adoption of a uniform and efficient system of quarantine for all exposed ports." This committee, consisting of Drs. J. C. Wilson, Chairman; E. O. Shakespeare, late U. S. Cholera Commissioner to Europe; and Dr. R. A. Cleemann, late member of the Philadelphia Board of Health, did its work thoroughly and well, and reported its results fearlessly and impartially.

It took up two main questions:

1. What are the requirements of an efficient quarantine against cholera?

2. To what extent do the existing arrangements at the Ports of New York, Philadelphia and Baltimore fulfil these requirements?

Their reply to the first of these questions, taken from an editorial in the *Medical News* of October 15, sums up these requirements so completely and concisely that I make no apology for reproducing it in full:

"Measures of prevention, to give the greatest possible guarantee of success in extinguishing an incipient epidemic of cholera, should, in the first place, be based upon the most exact knowledge we possess of the cause, mode of attack, and manner of spread of the disease; and, in the second place, these measures should be intelligently, thoroughly and rigidly enforced.

"What are the considerations involved in the first category? Probably nine-tenths of intelligent and experienced physicians all over the world, even including those of India, have for years admitted that there is most convincing proof that the active cause of the disease is a specific, material, living entity, of extremely minute size, endowed with the power of self-propagation, and of exceedingly rapid multiplication in enormous numbers; that among animals it naturally attacks man alone, assailing him only by way of the intestinal canal; that the evacuations from the bowels contain the active cause of the disease, and that when this agent in any manner—as through drinking-water, milk, food, the handling or washing of contaminated personal effects, etc.—reaches the intestines of another susceptible person, the disease may be thereby transmitted from the sick to the healthy; that the active agent exists in the dejecta of the lightest and most imperceptible, no less than in the severest and most deadly forms of the disease, and is known to be transportable from place to place through the movements of man and his personal effects.

"Proceeding from this basis, logical deduction and common experience alike demonstrate the absolute necessity and efficiency of such measures of prevention as the following:

"a. Speedy recognition and isolation of the sick; their proper treatment; absolute and rapid destruction of the infectious agent of the disease, not only in the dejecta and vomit, but also in clothing, bedding, and in or upon whatever else it finds a resting-place.

"b. The convalescents should remain isolated from the healthy so long as their stools possibly contain any of the infecting agent; before mingling again with the well they should be immersed in a disinfecting bath, and afterward be clothed from the skin outward with perfectly clean vestments, which cannot possibly contain any of the infectious material.

"c. The dead should be well wrapped in cloth thoroughly saturated in a solution of corrosive sublimate, 1 to 500, and without delay, cortege, or lengthy ceremonial, buried near the place of death in a deep grave, remote as possible from water which may, under any circumstances, be used for drinking, washing, culinary, or other domestic purposes. (Cremation, of course, is by far the safest way of disposing of cholera cadavers.)

"d. Those handling the sick or the dead should be careful to disinfect their hands and

soiled clothing at once, and especially before touching articles of food, and drinking or culinary vessels.

"e. In the case of maritime quarantine, the well should be disembarked and placed under observation in quarters spacious enough to avoid crowding, and so well appointed and furnished that none will suffer real hardships.

"f. Once having reached the station, those under observation should be separated in groups of not more than twelve to twenty-four, and the various groups should under no pretext intermingle; the quarters for each group should afford stationary lavatories and water-closets in perfect working condition, adequate to the needs of the individuals constituting the group, and supplied with proper means of disinfection. There should be a bed raised above the floor, proper coverings and a chair for each member of the group, each person being required to use only his own bed. There should be a common table of sufficient size to seat around it all the members of the group, who should be served their meals from a central kitchen, and with table furniture belonging to the station and cleaned by the common kitchen scullions.

"g. Drinking-water, free from possible contamination and of the best quality, should be distributed in the quarters of each group, as it is needed, and in such a manner that it is received in drinking-cups only; there should be no water buckets or other large vessels in which handkerchiefs, small vestments, children's diapers, etc., can be washed by the members of any group.

"h. Immediately after being separated into groups in their respective quarters, every person under observation should be obliged to strip and get into a bath (a disinfecting one is preferable), and afterward be clothed with fresh, clean vestments from the skin outward. Every article of clothing previously worn should be taken away and properly disinfected.

"i. Then all of the personal effects should be at once removed to a separate building, washed—if possible—and thoroughly disinfected, or, if necessary, destroyed. After disinfection they should be temporarily returned to the members of groups, when occasion requires a further change of clothing.

"k. Under no circumstances whatever should washing of clothing by those under observation be permitted. All used clothing should be first thoroughly disinfected (by boiling, when possible) and then should be cleansed, the disinfection and washing being done by a sufficiently trained and absolutely reliable corps of employes supplied with adequate appliances.

"l. All of those under observation should be mustered in their own quarters and be subjected to a close medical inspection, *while on their feet*, at least twice every day, in order to discover and

isolate as soon as possible new cases which may develop; and, of course, the clothing and bedding of these new cases should be treated without delay in the manner already mentioned. In the meantime a watch should be set over the water-closets, for the purpose of discovering cases of diarrhoea, and when discovered such cases should be temporarily separated from the rest; they should receive judicial medical attention at once, and precautions should be taken as if they were undoubted, but mild, cases of cholera.

"m. The quarters should be kept thoroughly clean, and every surface upon which infectious material could possibly be deposited, including the floors, should be washed with a strong disinfectant twice daily, and oftener when necessary; evacuations from the bowels should be passed into a strong disinfectant, the hopper of the closet should be then flushed, and finally drenched with a quantity of the same disinfectant.

"n. For the proper attention to the sick, there should be two or more competent and experienced physicians, assisted by a sufficient corps of intelligent and efficient nurses, with hours of duty so arranged that a physician with a sufficient number of nurses be in constant attendance in the wards of the hospital.

"o. For the prompt recognition and separation of new cases, their temporary medical attention, the proper treatment of discovered cases of diarrhoea or cholera, and of other maladies, and the immediate correction of every insanitary practice or condition by constant, vigilant and intelligent supervision, there should be at least two or more competent and experienced physicians, with hours of service so arranged that a physician is on duty night and day among those under observation; and he should have subject to his orders, at any and every moment, a sufficient and efficient corps of nurses and laborers to carry out properly and promptly his directions.

"p. In order to prevent the intermingling of the various groups, to enforce obedience and order, and to make it absolutely impossible for the quarantined and their personal effects to have any communication with the exterior, a well organized and sufficiently large police corps should patrol the borders of the stations and the buildings day and night.

"q. Any group among whom there has developed no new cases of cholera, or of choleraic diarrhoea, during the preceding eight or ten days, may be regarded as harmless, and allowed to leave quarantine after each one is finally immersed in a disinfecting bath and re-clothed with clean garments from the skin outward; the garments removed being destroyed, or thoroughly disinfected and cleansed as above indicated.

"As yet, no reference has been made to the crew, ship, and cargo. What has been said of the treatment of those under observation, applies

to every one of the ship's inhabitants. The observation, isolation, and cleansing of the crew and their effects, could safely be performed aboard ship if necessary. The ship should be thoroughly cleansed and disinfected, particular attention being given to the quarters of the emigrants and crew."

In regard to the second inquiry, it must be observed that it refers to the three most important ports of entry of the Middle States, if not of the country, and to those which are in most immediate and constant communication with the whole grand interior chain of lines of travel and traffic. And while I cannot accept the conclusion that "there is no reason to believe that the conditions of other ports of entry upon our Atlantic and Gulf coasts are in any respect superior," yet it must be admitted that the possible exceptions to this sweeping condemnation are extremely few. Passing over the minutia of the report of these inspections, which should be carefully read by every practical sanitarian, I make a few extracts from the general conclusions arrived at:

"It is evident that the quarantine establishments at Philadelphia and at Baltimore fail in the most essential requisites of the necessary number of properly equipped buildings for the isolation and observation of a large number of immigrants."

This is all the Committee say with regard to these ports. Could condemnation be more utter and complete. Its very brevity is appalling. Its language is very nearly that of a letter addressed by the speaker to the Board of Health of Philadelphia a short time previously, which says, "Permit me, however, at the risk of seeming pertinacity, again to call your attention to the *entire inadequacy of the provisions made by the State authorities* for coping with a similar emergency in our own port." They "are those of nearly a century ago, when the present metropolis of Pennsylvania was but a country town. What might have been the consequences to her teeming population had the ship 'Alesia' ascended the Delaware river to Chester, instead of anchoring off Sandy Hook, it is not pleasant to contemplate." New York, however, had a plant of sufficient dimensions to make it and its administration worthy of notice in detail. But so insufficient were the precautions and so defective the provisions there found, that the Committee felt compelled to record their verdict that,

"It would seem that if the importation of immigrants directly from a European port notoriously infected, is not to be temporarily prohibited as a necessity of public safety, or if the treatment of these immigrants after their arrival at the New York quarantine station is not to be immediately

and radically improved, our protection against an epidemic at the present time must rest mainly upon the fortunate circumstance of the near approach of a season in which the disease does not usually spread. The continuance of cholera among the passengers of the 'Alesia' so long after their removal to the station of observation, in itself demonstrates the inefficiency of the measures which have been adopted and enforced for its extinguishment there. Although we have not yet heard of the development of the disease anywhere on the main land, nevertheless, in view of the almost uncontrollable tendency of cholera to spread at times, and of the original insufficiency and the present faulty constitution of the police force on Hoffman Island, we feel impelled to believe that the immunity up to the present time has been owing to singular good fortune, rather than good management."

The report concludes nearly as follows: "It is natural, after having made our comments on the defects of the quarantine stations we have described that we should endeavor to point out their causes and probable remedy. There is one cause so prominent that we may dwell on that alone. It is the great expense. Were it not for the question of money there would have been physicians constantly in attendance at the New York station, and, consequently, better management and discipline would have been maintained, while at Philadelphia and Baltimore there would have been adequate establishments provided for the isolation and observation of large bodies of immigrants."

Municipalities and States are wont to scrutinize every dollar of their money appropriations, bringing their expenses down to the closest living limit. Quarantine in this country being, as a rule, enforced mainly against yellow fever and smallpox, a mistaken economy has caused no provision to be made for the more perfect establishments absolutely required for protection against cholera.

Philadelphia, Baltimore, and other ports of a more limited commerce, are unable to spend as much on their stations as is New York, with its large revenues from that source, yet an inefficient quarantine at any station exposes the whole country to the dangers of the importation of disease. But it is manifestly unfair that a single municipality or State should defray the expense of protecting the whole public.

How, then, can we have equally complete stations all along the coast? We believe that this can be effected by putting quarantine into the hands of the National Government.

Continuing its valuable labors, the committee proceeded to draw up "An address to the Medical Societies of the United States concerning the dangers to which the country is exposed by the ineffectual methods of quarantine at its ports, and in regard to the necessity of National control of

Maritime Quarantine." This address is based upon the combined results of Dr. Rauch's investigations and its own, and it aptly calls attention to the fact that an "inspection made during seasons of comparative quarantine inactivity" must of necessity be inadequate and misleading, and calculated to foster a false sense of security. Under the pressure of the emergency of a present contagion and thousands of suspects, glaring deficiencies instantly manifest themselves which were before unthought of. The general propositions submitted in the address, as a result of the consideration of existing conditions, are as follows:

First. "It is impossible adequately to protect the public health of the country against the importation of epidemic diseases by independent local maritime quarantine establishments."

Second. "A National system of quarantine is necessary."

Third. "A National organization would secure advantages not attainable by independent local quarantine establishments, however complete."

Among the subsidiary statements with which they reinforce these theses, I note the following:

"There is always great difficulty in obtaining sufficient appropriations of public money to defray the expenses of the necessary quarantine establishments and their proper maintenance. It is only possible, during periods of threatened invasion, to procure the considerable sums of money necessary for these purposes, whilst in the interim the money expended is greatly inadequate, though large sums are constantly needed. When the invader is at our gates it is often impossible to plan, construct or repair, and properly equip and garrison an efficient line of defences.

"Rival political and commercial interests are inimical to the perfect protection of the general public by independent and local quarantine.

"It is but natural that municipal organizations should, in looking after their own interests, pay little regard to the welfare of distant communities.

"In this connection may be noted the indisposition and failure on the part of local quarantine officers to notify the authorities interested of the arrival of emigrants from infected localities. Notwithstanding the frequent paramount interest of inland communities in the efficiency of the establishment and administration of quarantine at the seaboard, the local authorities of the latter frequently evince an unreasonable jealousy of any sort of investigation or suggestion looking to the general welfare.

"The benefits of quarantine inure to the welfare of the whole country; therefore, it is just that money should be as freely expended when necessary at one port as at another, without respect to their relative commercial importance. It is manifestly unfair that the seaboard cities and States should, as at present, be obliged to bear the entire expense of quarantine establishments

designed to protect the inhabitants of every region of the vast territory of the United States.

"A National quarantine, properly administered and conducted by trained officials accustomed to deal with contagious and infectious diseases, would tend to prevent panic, to allay undue anxiety, and to favor a reasonable sense of security.

"Experience has shown that much needless alarm, as well as preventable danger, arises upon the appearance of an unfamiliar epidemic disease at quarantine stations; as when cholera has shown itself at New Orleans or New York, or yellow fever at Philadelphia or Boston. A National quarantine would go far to do away with the necessity for vexatious temporary interstate quarantines, which so seriously disturb inland trade.

"A National quarantine system, directed in such a manner as fully to meet the requirements of existing sanitary knowledge, would not adversely disturb any commercial interest. It would, on the contrary, do away with many of the embarrassments incident to maladministration of existing local regulations. For example, the healthy passengers of the Italian steamship *Alesia* were detained at quarantine in New York harbor for a period of fifty-eight days, while under an efficient system uninfluenced by needless fears, those of them who were free from disease could have been safely liberated in ten days at least."

The committee thus sums up its conclusions:

"*Summary.*—Under the present system of local and independent maritime quarantine, the necessary quarters for the detention of large numbers of immigrants arriving in a suspected vessel, are either entirely wanting, or, if at hand, are deficient in equipment or administration, or both. It is possible, however, that one port well governed and rich from prosperous commerce, may make up these deficiencies; yet what would this avail even to that community itself, if a neighboring port, only a few hours distant by rail, failed to exclude epidemic diseases? The front door might be doubly barred and bolted, but the enemy would find an easy passage through the defenceless rear. As recent examples thereof may be instanced the danger of an epidemic of yellow fever to which the little town of Biloxi, in Mississippi, exposed in 1886 not only the interior States, but even the city of New Orleans itself, now apparently so well protected by her own system of maritime quarantine; and that to which, in 1887, the defenceless condition of the small port of Tampa, in Florida, exposed not only that State, but others.

"This want of uniformity in the quarantine defences along our coast must necessarily exist when different authorities supply the money for maintaining the several stations, and the purse of one port is longer than that of its neighbor. Another money difficulty is found when the appropriation for the same station comes, as it may, from the coffers of both city and State: possible difference

of opinion in the municipal council and the State legislature is likely to endanger the sufficiency or change the direction of the funds to be expended. In any case, the danger to a single port of entry, or even to a single State, is by no means the same as that which threatens the country at large, and communities are not likely to make a larger expenditure than is needed for their own defence. As an illustration of the difference in the conditions of danger which may exist between the port of entry and the interior of the country, may be mentioned the passage of immigrants with infected baggage. The immigrants may come from a healthy port and in a healthy ship, and with the poison securely imprisoned in their baggage, will pass through the port of entry with perfect safety to its inhabitants; the danger will begin in that far interior where the baggage is opened. It is of no interest to that port to have the baggage disinfected, and it is carried on to some uncertain place unhindered to do its fatal work. And here may be pointed out the rather peculiar position in which America finds itself, in attracting to its shores hordes of immigrants from the older countries. There is in municipalities little disposition to spend more even than is called for to satisfy immediate wants; remote necessities are seldom provided for. A quarantine that is not always in use, is not always ready for use. It is only when danger is at its gates, and when, perhaps, it is too late for protection, that a city wakes up to its defenceless state. Municipalities are selfish, and knowing that with the trader quarantine is not a favorable institution, and that it is his tendency to sail into that port where the quarantine is most lax, they are assailed with a sore temptation to wink at the neglect of proper precautions if, by so doing, they may circumvent a possible commercial rival.

"In the opinion of the committee, the difficulties mentioned can only be overcome by the adoption of a maritime quarantine under the control of the National Government."

Commenting upon this report, in its issue of Nov. 5, 1887, the *Medical News*, of Philadelphia, pertinently says:

"As the testimony of thoroughly competent and independent observers, a committee of one of the most conservative and respected medical bodies in America, it carries with it the weight of conviction, and conclusively proves the urgent necessity of a radical reform in our method of guarding the country against devastating epidemics with which we are, through foreign communications, from time to time threatened.

"Should the germs of cholera finally escape or be permitted to pass beyond quarantine, they may not limit their onslaught to the nearest city, but may spread over the land and ultimately carry sorrow and loss to homes hundreds, and even thousands of miles distant from the port where they entered.

"The abuses and the faults of an exclusively local quarantine, such as at present exists, are so natural and intrinsic that we should, by this time, acknowledge the absolute need of a National protection of the general welfare by a National maintenance and administration of quarantine."

Meantime, the entire country appears to be waking up to a sense of the urgent need for immediate and definite action in the direction indicated. The Senate Committee "on Epidemic Diseases, in relation to Seaboard Quarantines" has had under consideration during the present session the following bills, resolutions and memorials:

Senate Bill 665, "To establish a quarantine station at the port of San Francisco;"

Senate Bill 1641, "To establish a permanent quarantine station at or near Cape Charles, Virginia;"

"Resolutions of the Legislature of the State of Virginia in the nature of a memorial, asking the establishment of a quarantine station at Cape Charles;

"Resolutions of the Board of Trade of Chester, Pa.;

"Petition of the Board of Health of Rockford, Ill.;

"Resolutions of the Board of Health of Charleston, S. C.;

"Petition of the Medical Society of San Diego, Cal.; and

"Resolutions of the American Public Health Association;

"All urging the establishment of national quarantine at the points of danger upon the Gulf and seacoast."

The Committee expresses its belief "that it is the duty of Congress to so regulate commerce as to prevent the introduction of contagion from foreign countries into the United States, and has therefore reported, with favorable recommendation, an original bill providing for the establishment of seven thoroughly equipped quarantine stations in addition to the one already provided for at the mouth of the Mississippi river, viz: at the Delaware Breakwater; Cape Charles, Va.; Sapelo Sound; Key West, Fla.; San Diego, Cal.; and Port Townsend, Oregon.

"The estimated aggregate cost of construction and equipment of these quarantine stations, including the one at the mouth of the Mississippi river, is \$489,500, and the estimated aggregate annual cost of maintaining them is \$93,000.

It is not conceivable that when once the National Government has committed itself so far both in policy and expenditure, it will long delay the extension of this system northward, and the making it uniform throughout the entire coast line. Of course there will be differences of opinion, as to whether the bureau into whose hands would fall the superintendences of these

stations under the existing law, is the appropriate one, and whether the preservation of the public health is not an interest of sufficient magnitude to entitle it to a department of its own. But when such substantial safeguards are offered us, it would not be the part of wisdom to reject them on merely theoretical or sentimental grounds. Consider for a moment the unprotected condition of the Delaware river as revealed in the reports referred to; ascending the bay and river a distance of nearly 80 miles before the Pennsylvania or Philadelphia quarantine station is reached, through a populous country, passing numerous villages, and two considerable cities, with no other restrictions than the local regulations of the coasting trade; the Philadelphia quarantine station situated close to a large and rapidly growing city, whose Board of Trade have already taken the alarm and protested in a memorial to Congress against the dangerous contiguity; and yet, both the State of Pennsylvania and the City of Philadelphia are utterly powerless to remove it to a better and more distant location, from the simple fact that the boundary of the State is only a few miles lower down the river, and the entire intervening distance along the river bank is one continuous settlement. The only proper site for a quarantine station is within the limits of the little State of Delaware, and the expenditure necessary to establish and maintain a properly equipped station for the protection of Pennsylvania, New Jersey and the "parts beyond" would drive her into immediate and hopeless insolvency. There are but two solutions of this pressing problem: Either the National Government must promptly establish a well-appointed quarantine down the bay, or the three States of Pennsylvania, New Jersey and Delaware must form a tripartite alliance, and unite in defraying the expense of protecting themselves and the nation against their common foe. It is a question, however, whether this would not be establishing an *imperium in imperio* which would be more defiant of constitutional restriction than the federal interference for which it would be a substitute.

In conclusion, I beg leave to offer the following resolution:

Resolved, That the Section on State Medicine respectfully suggests to the American Medical Association, the importance of formally urging upon the National Congress the duty of at once assuming entire control of maritime quarantine, and of taking immediate measures to make such quarantine effective before the advent of hot weather.

DR. J. B. HAMILTON, Surgeon-General U. S. Marine Hospital Service: Let us consider for a moment the actual state of affairs; the condition of the countries quarantined against. The purification of Calcutta would only purify the local

region; Bombay and the entire Presidency was as much infected with cholera as Calcutta. The time will come when the International action consequent upon International sanitary conferences will alleviate this condition, as the quarantine which had been established at the Red Sea entrance of the Suez Canal, and which was continued by recommendation of the last International Sanitary Conference. Public sentiment would prevent the existence of a cholera breeding spot at Calcutta, and one of yellow fever in Cuba. In the meantime, shall the National or local Government do the work in this country?

Where the commerce was large enough for the revenue from the quarantine inspection service to support it, the State would wish no change made. But when, as at Philadelphia, Pennsylvania would have to enter into a treaty with New Jersey and Delaware, in order to enforce quarantine, it seems to me the intervention of the National Government would be preferred. Vessels coming to Delaware Breakwater with small-pox cases on board left them at Lewes, Delaware, where they took the train and proceeded to the heart of the city of Philadelphia. To-day no perfected quarantine existed on the Pacific coast. Petition after petition has come to the Treasury Department, requesting interference in behalf of passengers detained on infected vessels. A year or two ago yellow fever patients were found walking in the streets of San Francisco. Even now cholera is in Chili. It was introduced into South America in a criminal manner; a high official wishing to land from an infected vessel, and cholera patients went ashore with him.

Regarding the constitutionality of Congress to enact epidemic laws, this question has arisen under the very bills referred to. The Senator best informed on quarantine matters said that Congress had no right under the public welfare clause of the Constitution to enact such laws. But under that section authorizing Congress to enact laws regulating commerce, the Senate now passed these bills. The law of 1878 allows the making of quarantine regulations, which, when approved by the President, and not in conflict with existing laws for the preservation of the public health, are executive orders and have the force of law.

The old law provided no penalty for vessels bringing contagion, or for violating its provisions. The proposed law provides a fine of \$300 on a master of a vessel or other person who brings in infectious disease, or who violates the regulations framed in accordance with the act. It also provided a penalty for trespass on quarantine grounds. The proposed quarantine stations are to be located at Delaware Breakwater, Norfolk, Sapelo Sound, Key West, San Diego, San Francisco and Port Townsend. To provide for these quarantines boats, disinfecting machinery, hospital buildings, etc., an appropriation of \$480,000 had been asked. It was

estimated that the expenses of administering these stations would be \$90,000 per annum. In order to have no delay the estimate for the existing fiscal year had been included in the appropriation asked for. Heretofore the quarantine appropriation has been contingent.

With cholera in Europe, yellow fever in the West Indies, and small-pox threatening from various points, it could be assumed that the danger always existed.

At the request of the Louisiana State Board of Health I have directed one of my officers to go to New Orleans to make a thorough inspection of the quarantine at that port. In case the test should prove to be satisfactory, the machinery will be duplicated at each of the proposed quarantine stations. Of course this is dependent upon the House of Representatives passing the bill which has been enacted by the Senate.

DR. HIBBARD, of Indiana: Is the House of Representatives in favor of making the appropriation?

DR. HAMILTON: I know of no opposition, but in order to secure speedy action on the bill support is needed. In accordance with a law passed last March a Board composed of Dr. Wilkinson, the President of the Louisiana State Board of Health, two officers of the Marine Hospital Service, and an officer of the Revenue Marine Service, have selected Chandeleur Island as the most advantageous site for the Gulf quarantine.

One thing I should have mentioned as needed at the proposed quarantine stations is well equipped bacteriological laboratories. The cordial co-operation of the medical profession is earnestly desired. There is no desire to interfere with local quarantines; the latter will have to equal those of the United States, or in the event of the demonstrated efficiency of these, public sentiment will demand their substitution for local quarantines.

DR. ORME, of California: I am pleased to hear so fully from Dr. Hamilton. We all know the importance of this subject, and I would like to know what pressure is necessary to secure the desired end.

DR. LINDSLEY, of Tennessee: I move that a committee be appointed, of which Dr. Lee be the chairman, to draft a resolution for presentation to the Association, petitioning Congress to take immediate action on the law.

THE ANTIPYRETIC, AND THE ABORTIVE TREATMENT OF TYPHOID AND REMITTENT FEVERS.

Read before the Wisconsin Medical Society, June, 1888.

BY J. R. BARNETT, M.D.,

OF NEENAH, WIS.

CHAIRMAN COMMITTEE ON PRACTICE OF MEDICINE.

(Concluded from page 447.)

Out of a total of about 100 of these cases, including more than seventy of typhoid, only two died. One of these, already reported, suffered an enormous epistaxis on the seventh day, following repeated bleedings before, and died on the ninth. The treatment of this case was mostly by quinine, on account of the hæmorrhage; which, it may be remarked, was the only alarming symptom which presented.

The other fatal one had an intestinal hæmorrhage on the third day of sickness in bed, with a coincident fall of temperature to 99°. The patient died suddenly early next morning, before I saw him. An autopsy was not permitted, and the cause of death is therefore conjectural. I was told by the family that his physician had some years before diagnosed fatty and enlarged heart. He had been a hard drinker for many years, and for this reason I had allowed stimulants throughout his short sickness.

The early occurrence of hæmorrhage is interesting, unless it be assumed that the patient was somewhat advanced in fever before he took to his bed. It is not improbable that a large concealed hæmorrhage contributed more to the sudden death than did the fatty heart.

Having now presented all the striking cases, and the worst ones, occurring in the last series of two years, without, however, going into daily clinical details which might unnecessarily prolong this paper, I shall draw upon the current literature of the subject for facts reported by other, and perhaps less partial, observers. These have accumulated during the past year to an amount that gives them decided value, even from the statistical standpoint, but more still for the broader therapeutic basis they have given the ammonium salicylate, and for the elimination of an important error of opinion to which its earliest use led.

This error, first pointed out by Dr. J. D. Sullivan, of Brooklyn, N. Y., consisted in ascribing stimulating properties to the salt, whereas its effects are undoubtedly sedative and depressing. It ought to be explained, however, that the mistake arose naturally from the manner in which the remedy was extemporaneously prepared. At that time there was no ammonium salicylate, so far as I knew. It had to be extemporized by the druggist, and sometimes the mixture would contain the salicylic acid and ammonium carbonate in the proportion of three to two, varying all the way to equal parts, according to indications for stimula-

VACCINATION AND REVACCINATION. — M. PROUST, in a report to the Académie de Médecine, shows that the question as to the utility of vaccination and revaccination is about solved. In Germany, where vaccination is compulsory, small-pox no longer occupies a place in the statistics of the causes of death. The death-rate from small-pox in Berlin is 1.5 out of 100,000 inhabitants. In Paris the rate is 136, or 4000 a year.

tion presented by the case in hand. But both of these proportions represent the carbonate of ammonia in excess, and the last and commonest proportion represents an excess great enough to constitute the mixture a stimulant under most circumstances.

Besides, the use of such a mixture enabled one to dispense with alcoholic stimulants, which had hitherto been a necessity, and so the error, such as it was, was confirmed.

I was interested to observe that Dr. Sullivan, who first announced the depressing effect of the neutral ammonium salicylate, corrected this effect by adding the aromatic spirits of ammonia.

His interesting paper on the therapeutical effects of this salt, read at the annual meeting of the Fifth District Branch of the New York State Medical Association, and published in *Gaillard's Medical Journal* for July, 1887, related mainly to cases of erysipelas, septic cellulitis, puerperal septicæmia and the septic fever of tuberculosis; in which he affirmed the antiseptic and antipyretic effects of the remedy were strikingly shown; but he had had the opportunity to employ it in only one case of typhoid. This displayed all the general characteristics of the disease, with a temperature of 102° . Prescribing 8 grs. of the salicylate every four hours, after a small dose of calomel, he found "on the next day his (the patient's) temperature was reduced to 100° , his skin was moist, and he expressed himself as feeling somewhat better, and the following day his improvement was quite evident, and the ammonium salicylate was reduced to 8 grs. four times a day. He continued to improve daily, and to my surprise," the reporter adds, "I found him dressed and sitting up. His temperature was normal and he complained of nothing but weakness; he continued to improve, and within two weeks from the time of my first visit he was able to return to his business."

It is, however, mainly from his experience with this agent in septic fevers of inflammatory origin that Dr. Sullivan draws, among others, these conclusions:

"It is certainly a very effective antipyretic. In certain diseases of septic origin it exerts a curative action by tending to retard, and possibly inhibit, the development of septic elements in the system.

"It will not reduce the temperature as rapidly as antipyrin or antifebrin, but the antipyretic effect is more lasting than that produced by either of these agents."

Dr. Oscar A. Fliesburg, of Hudson, in a paper read before the Inter-state Medical Association during the meeting of last July, and published in the *Therapeutic Gazette* of the following October, records the results of his own experience with this remedy in typhoid fever and the fevers of the puerperium, as well as in most inflammations of the respiratory tract, with a positiveness of conclusion

not to be mistaken. Extemporizing the salt with a large excess of ammonium carbonate—two of the latter to one of the acid—he gave it in doses reaching 15 grs. or more, to be repeated as needed every hour or two. He says: "I have with these doses been able to reduce temperature in a short time from 105° or 106° to 99° or 100° , and by repeated doses at longer intervals been able to keep the temperature down at that point. At the same time my cases have progressed without much other medication to a favorable end in a shorter time, and with less distress to the patient, than by the older methods." In general terms he says: "The fact stands undisputed and proven that we, in salicylate of ammonium, possess a sure remedy to reduce temperature, and by its germicidal and antiseptic properties able to abort and shorten the zymotic diseases."

In a paper entitled "Salicylate of Ammonium for Fevers," which appeared in *THE JOURNAL* of February 11, 1888, Dr. D. M. Wick, of New Hartford, Iowa, gives the clinical histories of several cases of remittent fever, from which I will make brief extracts.

A boy of 6, with a temperature of 102° to 103° , was put upon calomel, to arouse the secretions, quinine, as an antiperiodic, and sweet spirits of nitre as a febrifuge, with the effect that a bright scarlatinal rash, with œdema of hands and feet, and intense itching, were produced, without any favorable effect upon the fever, which increased to 103° and 104° on the fourth day of treatment. This was now changed to ammonium salicylate, 2 grains every two hours, unaided by any other remedy. Dr. Wick adds: "I saw the patient again in eight hours, and found him with temperature reduced to 99.5° , resting quietly and sweating profusely. Next day the temperature was normal, the boy feeling so well that he wanted to be up and dressed. He made a rapid recovery."

Another boy, æt. 5 years, had been sick with remittent fever nearly a week when first seen. He was given the orthodox treatment for a week more, the temperature never falling below 102° , skin hot and dry all the time. Dr. Wick continues: "I again dropped all other drugs and gave salicylate of ammonium, gr. ij every two hours. In about eight hours his temperature fell to 99° , and he was bathed in perspiration. Continued the dose once in four hours. Saw the case next day and found no fever; tongue clean, skin moist, and the boy in every respect improved. He had no relapse, and was soon able to be around."

A girl 11 years old had had a run of measles, but fever continued high (102° to 104°), diarrhœa supervened, sordes appeared, and semi-delirium, with a temperature of 105° . When these had continued five days, the case assuming a very serious aspect, the salicylate was substituted for all other remedies, in the dose of 2 grs. every hour.

Says Dr. Wick: "The nurse told me the next morning that after giving the fourth dose the patient began to sweat, and by the time the fifth was to be given her clothing was so thoroughly saturated that the time was lengthened to four hours. Her temperature was normal. From this time she gained rapidly without one unfavorable symptom, and in one week was up." Concluding his report the doctor says:

"What is there in salicylate of ammonium that arrests high fevers so abruptly? Had the quinine, in the two remittent fever cases, neutralized all malarial poison, and, when the salicylate was given, ushered in the sweating stage? Or was it the germicidal, antiseptic and antipyretic powers of the salicylate that acted so happily? There is a *something* in its make-up that subdues arterial tension and chemically destroys the microorganisms in the blood."

In THE JOURNAL of March 3, 1888, appears a communication from Dr. D. L. Sauerhering, of Wausau, describing an endemic of typhoid, somewhat atypical in clinical history, which occurred in that city last season, and adding some comparative notes of treatment. In these he says: "Quinine, natr. salicyl. and antipyrin did not act satisfactorily in my hands, for, if given in doses large enough to depress the temperature, it would remain so only for a short time, returning to its original height in the course of ten or twelve hours, notwithstanding the constant administration of the antipyretic.

"The remedy *par excellence* proved to be the ammonium salicylate. It invariably reduced the temperature to 99°-100°, keeping it there during the entire course of the disease, diminishing the rate and force of the pulse and causing, in the majority of cases, profuse diaphoresis. When given early, within the first few days of manifestation of disease, it would generally break up an attack, the patient being able to be up and about the house in two or three days." In cases not seen until the beginning of the second week such drugs as were indicated were added to the treatment, *c. g.*, digitalis, potassium bromide, turpentine and opium.

He relates a case to illustrate the prompt action of the drug:

German, 21, laborer, seen on the ninth day of fever, at 7 P.M. Face flushed, skin hot and dry, pulse hard and full, 120; temperature 105.2°. There was considerable tenderness along the course of the colon. He was placed upon a mixture containing ammon. salicyl., gr. viij; tr. aconiti, gtt. j; potass. brom., gr. vj; ext. ergot, fl. gtt. iij, to be given every two hours. Next day at 10 A.M. his temperature was 97.8°, pulse soft and full, 96, he was perspiring freely and was free from headache. His medicine was reduced one-half and, as there was constipation and dryness of the tongue, castor-oil and turpentine were

prescribed. Two days after this Dr. Sauerhering found his patient out of bed, and one week afterward able to do the chores about the barn. "His temperature never rose to above normal after the first decline."

Continuing, the doctor says: "I am unable to give an explanation of the action of this drug, but can say from experience gathered at the bedside that it has proved itself to be a very efficient remedy in the treatment of this disease—shall we call it typhoid? Some undoubted cases of typhoid occurred during the time."

Some general remarks as to the manner of administering the ammonium salicylate, and as to immediate effects, should be offered in conclusion.

In general terms, the dose of the salt is very near in size to the antipyretic dose of the acid, although not so large, for while the former is by far the more active germicide, it is also the better antithermic. The extemporaneous preparation of the salt from the acid and ammonium carbonate shows, after perfect evaporation, that it weighs but a trifle more than the acid employed; that is to say, enough water and carbonic acid disappear in the reaction to nearly equal in weight the ammonium carbonate. The preparation of it is one of the simplest tasks of pharmacy, for it is not necessary that exact equivalents should be prescribed, as a slight excess of the carbonate is almost always an advantage. Two parts of the latter to three of the acid represent such a slight excess, and the following formula is a convenient routine prescription:

Acid salicyl.	5iij.
Ammon. carb.	5ij.
Aq. menth. pip.	5iv.

A teaspoonful of this given every two hours until its effects upon temperature are secured will usually be enough, although this quantity may, in many cases, be doubled. Symptoms of marked asthenia occurring early or late would make an increase in the ammonium carbonate necessary, but it is very seldom that it should exceed the acid in weight. On the other hand, in certain irritable states of the stomach any alkaline excess is objectionable, and a solution virtually neutral would be preferable. Such a solution would be obtained by taking out of the above formula 20 grains of the carbonate.

But it is to be said in favor of this salicylate that it is better borne by the stomach than any other with which I am familiar, and for this reason is often substituted to advantage for the sodium salt in the treatment of rheumatism, and the few inflammations in which the latter is commonly preferred.

Now and then, where constipation is present, it seems to act as a laxative, although it seldom or never increases the symptomatic diarrhoea of the fever. On the contrary, it has often seemed to lessen the frequency of the intestinal discharges,

while unmistakably modifying their character for the better. Indeed, this effect would alone justify the use of the remedy in the majority of cases of typhoid, were there no more cogent indications for it to fulfil. Dr. Sullivan has well pointed out the analogy of such treatment to the antiseptic treatment of infantile diarrhoeas by sodium salicylate, naphthalin, etc., as recommended by Hutchins, and others. It is not pertinent to the question, but I may add that Dr. Sullivan has substituted the ammonium for the sodium salt in these infantile cases, for the reason that "it is much less irritating and depressing."

The supposed laxative effect in fever cases characterized by constipation, is susceptible of another explanation—the natural evolution of the disease. But this symptom, whether artificial or natural, is always short-lived if it occur after the patient has been under care three or four days, that is to say, when there has been the opportunity to avert the severer abdominal lesions. When these have occurred,—when there has been considerable infiltration of the intestinal glands, or any degree of softening or ulceration, the time has gone for anything more than the palliation of this symptom in common with the associated symptoms of the fever. Stated in words this appears a trifle. At the bedside it is by no means a trifle. Let it be remembered that it is one of the maxims of the expectant treatment of typhoid that the diarrhoea is an eliminative process not to be interfered with. But intestinal disinfection and antiseptics, to the degree secured by the salicylate, not to mention its anterior effect upon the system at large, change the conditions of the case, and render what were otherwise a conservative evil, a needless evil. Now, with the help of a minute dose of opium given regularly, or a larger one given occasionally, the diarrhoea can be partially checked, and the business of elimination left to the renal and cutaneous emunctories.

Excretion by both of these channels is undoubtedly greatly stimulated by the salicylate. One of its earliest and most persisting effects, noted by all observers, is the free and often annoying diaphoresis, which accompanies, or even precedes the decline in temperature, and continues when the salt is given to maintain a normal temperature once reached.

The effect upon the kidneys is not so striking but is just as unmistakable. The quantity of urine is augmented, and it soon grows lighter in color and less offensive in smell. That this does not indicate a lessened excretion of solids has not been determined chemically, but it can be easily and surely inferred from the mental state of the patient. Delirium and coma-vigil are lessened to a marked degree, and in many cases averted altogether. Subsultus and carphologia, which often used to occur too early to be mere symptoms of adynamia, are now seldom observed, or only for a

few days. All this goes to show that an avowedly germicide and antiseptic treatment may do more to promote excretion, even while lessening the need for it, than the professed eliminants.

Headache is often relieved to a degree out of proportion to the temperature ebb. That this comes in part from an analgesic property of the salt has been proven in the different headaches of apyrexia.

Sleep is promoted; less, probably, from any hypnotic effect than from its modifying effect upon the general conditions pertaining to the fever. But in a word it may be said that the comfort of the patient is in every way promoted; every way save one. The one discomfort of its own that the salicylate brings is the ringing in the ears, which is so unpleasant to many that it is to be hoped that some remedy for it will be speedily found.

The cases observed during these four years have been singularly exempt from complications. The only case of intestinal hæmorrhage was the one reported. I do not recall a case complicated by pneumonitis or femoral phlebitis and thrombosis, nor, it is hardly necessary to add, of peritonitis from intestinal perforation. I do not speak of the absence of any one of these complications as singular; it is the exemption from all. Regarding the commonest one, pneumonia, we may say this, that whether we adopt the view of Klebs, that it is caused by the direct access of the bacillus typhus through the respiratory tract, or the more probable one that it is a septic inflammation from the hæmic contamination incident to the fever, that any germicide and antiseptic inhibitory of these agencies will as easily arrest the pneumonia as it will abate the fever. So if glandular infiltration is interrupted, and ulceration is prevented, there will be no intestinal hæmorrhage, no perforation, no peritonitis.

What of auxiliary treatment? Such treatment is very rarely required. In not more than one case in twenty has the question whether it were not well to give stimulants ever occurred to me. There is a general appearance of well-being and well-doing to the patient that is sufficiently reassuring to the physician without the need of extra precautions. Almost equally seldom will the question of giving quinine arise. A tonic seems as unnecessary as an alcoholic stimulant, while as an antipyretic quinine might certainly be left out of the question.

It would seem that laxatives, and especially cathartics, might be almost wholly dispensed with, unless it should appear that prolonged constipation had preceded the onset of the fever. Even then the laxative could be selected without any reference to antiseptic effects, so that the choice need not of necessity fall upon calomel. Its antiseptic effect would not add appreciably to that already attained by the salicylate.

Opium will find a useful place oftener than any other adjuvant; but as already intimated, it will be needed less than under former modes of treatment, while on the other hand, a safeguard is guaranteed for a much freer use, since the constant maintenance of free elimination is not now of such vital consequence.

To raise the question of the mode by which ammonium salicylate interrupts the course of typhoid and remittent fevers would, at the present time, be but to open up a field of boundless conjecture. This will have to be determined by future investigations, and by those qualified by experience in such researches. Still, I cannot forego expressing the belief that when this and similar questions are cleared up the conclusion will be in harmony with the views advanced by Professor Semmola before the Ninth International Medical Congress. "The true part played by bacteria in pathology" he says, "is the production by them of certain noxious and decomposed elements of the blood, which substances, and not the bacteria, are the potent factors in the causation of disease."

Not forgetting the cause of this cause, it is still probable that all the striking phenomena of these fevers proceed directly from this condition of the blood, this *ptomainemia*, if we may use such a word, and it is at least presumable that the phenomena may be interrupted or averted by chemically changing those ptomaines, or undetermined noxious substances, so as to render them innocuous, and that without necessarily destroying the vitality of the bacteria causing them. The very unstable nature of these substances already known would invite such a mode of attack, and would justify the use of the feebler germicides, capable, nevertheless, of decomposing these substances.

While believing that the ammonium salicylate reaches the first cause of these fevers by a destructive or inhibitory action upon their specific germs. I believe also that this is likely to prove the lesser of its two leading effects, being led to this view by the clinical fact, reported two years ago, of the recrudescence of the fever when the salicylate is prematurely dropped out of the treatment, as at any time before the end of the first week. This, occurring after a day or more of normal temperature, would argue a re-intoxication by the products of the vital activity of bacteria still living; which is equivalent to saying that the bacilli may be present without fever so long as their immediate effects are neutralized, just as they may be present without fever when their vitality is seriously compromised.

Do the foregoing facts justify the conclusion that ammonium salicylate is a specific remedy for typhoid and remittent fevers? I think they do. The advocates of the iodine treatment of typhoid advance the unchallenged claim that it is a specific, while Liebermeister has shown that it is attended by a mortality of more than 14 per cent.

Ziemssen admits the same claim for calomel, while denying that it is able to shorten the disease; but the mortality following this treatment is nearly 12 per cent. The mortality for the cold-water treatment, as reported by Brand, of Stettin, out of a total of more than 8,000 collected cases is 7.4 per cent. Under all modes of treatment, as determined by Jaccoud from more than 80,000 cases, the fatality is, 19.25 per cent. Up to the present the mortality percentage for the ammonium salicylate treatment is somewhat less than 3.

It will undoubtedly be objected that cases ending in resolution during the first week, or before pathognomonic symptoms of the fever have time to develop, cannot be fairly classified as typhoid. This is a rational objection, but it holds equally against all statistics of specific treatment; for no medication with a view to aborting the disease many days later than this period will be availing. If then we are to await the occurrence of the distinctive anatomical lesions before being permitted to announce a diagnosis, it is clear that no remedy, now or hereafter, can successfully claim to be abortive or specific. It ought to be a basis for a diagnosis having all the elements of probable correctness, that a given case has occurred during the prevalence of typhoid, especially in the same family; that the usual prodromata have been present, and that high fever, characterized by the usual thermometric curve has existed for two or three days.

While it is possible that my diagnosis has not always been subject to these limitations, it is certain that the exceptions have been very few.

It must be admitted that the number of cases has been too small to have great statistical value, but they cover a period of four years, and so represent the average severity of the disease, whereas the same number occurring in the course of an epidemic might represent only a benign form of the malady, where the fatality would be light under any treatment, or without any.

If the consideration of the treatment of these two fevers in a single paper needs an explanation or apology it is this:

Save in unimportant particulars the treatment is identical. Both are arrested by the ammonium salicylate; such arrest being limited to the pre-inflammatory stage of typhoid, while it is doubtless practicable in any stage of remittent fever. This is so probable that it may serve in the differential diagnosis of cases hard to make out—cases which occur with sufficient frequency to the most careful and observing clinician. It may be fairly assumed that in a case of supposed typhoid, seen first after the occurrence of striking abdominal symptoms, and shortly aborted, a revision of diagnosis is warranted if not demanded. At the same time it is *practically* unimportant to make the distinction, since the revision, when made, involves no corresponding change of treatment.

RENAL TENESMUS:

A RESULT OF CHRONIC CYSTITIS AND URETERITIS: SUCCESSFUL TREATMENT BY KOLPO-URETERO-CYSTOTOMY AND INTRAVAGINAL DRAINAGE COMBINED WITH ELEVATION AND SUPPORT OF THE UTERUS AND OVARIES.

Read in the Section on Gynecology, at the Thirty-ninth Annual Meeting of the American Medical Association, May, 1888.

BY NATHAN BOSEMAN, M.D.,

SURGEON TO THE WOMAN'S HOSPITAL, NEW YORK.

(Concluded from p. 443.)

Ureteritis and Pyelitis.—I have referred particularly in the preceding remarks to the teachings of my first operation of kolpo-cystotomy, in 1861, and to those of the recent case cited, because they have a direct bearing upon ureteritis and pyelitis, belonging to the third and fourth classes of our division. They show the tenor of the line of work that I have pursued during all the succeeding years of my experience, which has finally led me to diagnosticate, differentiate, and treat successfully the two last named diseases. This has been done by a careful study of certain groups of symptoms and physical signs characterizing these and other lesions sketched in the first part of this paper. I will again briefly point out the more important differences between ureteritis and pyelitis. Ureteritis indicates its presence by congestion and thickening of the mucous lining of the vesical portion of the ureter, and by diminution of its lumen, coupled at times with intense morbid sensibility. Pyelitis evinces a thickening or hypertrophy of the walls of the ureter in some part or the whole of its extent, with partial or complete dilatation, coupled with no greater sensibility usually than accompanies the lodgment of a similar sized instrument in the male urethra for the relief of a stricture.

I am sorry that time does not permit me to report all of my cases of these two classes, in order to illustrate and substantiate more fully what I have said. Each presents certain points of interest, but at the same time there is a uniformity in the principal features of all. The case of Mrs. B., already related in the journal cited, I regard as typical of my fourth class, where dilatation of the ureter had occurred and the inflammation had extended to the pelvis of the kidney.

Kolpo-Uretero-Cystotomy.—By kolpo-uretero-cystotomy, described in my paper on the treatment of chronic pyelitis, and now advocated and recommended for the successful treatment of renal tenesmus, I mean the making of an opening through the vesico-vaginal septum not smaller than a silver half-dollar, and having specific and close relation to the outlet of the affected ureter and kidney. When of this size and in this situation, it insures a free and direct escape of the secretions from both organs into my intra-vaginal drain, from which a state of the most complete physiological rest is obtained, with the best pos-

sible aseptic surroundings of the newly-made wound. In this way the greatest comfort is conferred upon the patient in any position she may choose to take for sleeping, sitting or walking.

While it may seem to some, with no experience in such matters, that my recommendations for the establishment of the large openings in the two procedures outlined shows a needless sacrifice of tissue, with which I have, indeed, been charged by writers with regard to the first, yet, nevertheless, I am prepared to maintain the correctness of the practice on the basis of the good results I have obtained by them, and from having seen very defective vesical drainage and the evil consequences therefrom, when even larger fistulous openings existed than I have advocated, resulting from parturition. It is well to bear in mind that I operate either in the supported knee-elbow or left lateral position, using my bilateral dilating speculum, which spreads out the septum, very elastic in character, and the opening when made in it in this state of tension naturally seems large. From these circumstances it may be readily inferred that the loss of tissue is always more apparent than real.

Renal Tenesmus.—This brings us now to the study of renal tenesmus as a result of chronic inflammation of the mucous membrane of the vesical portion of the ureters, the main object of this paper. By renal tenesmus I mean violent and painful contractions of one or the other ureter and corresponding pelvis of the kidney, with marked tenderness or soreness under pressure of the latter organ, proceeding from morbid irritability of both structures. The pains occur in paroxysms, which vary in frequency, duration, and severity in different cases according to the stage of the preceding ureteritis and the extension of the lesion to one or both sides. As a rule, it is confined at first to the groin on one side of the body, and afterward to the corresponding lumbar region. In the more severe attacks the pain, besides being violent in these situations, radiates to the hip, the outer and inner sides of the thigh, the knee, leg, and even to the toes. Cramps of the muscles of the lower extremity on the affected side also occur in these severe paroxysms. In the well-marked cases, attacks of this sort come on daily, or even several times a day. They are most frequent and severe during the menstrual periods. The patients describe them as occurring most often during the night. They awake with a pressing desire to urinate; the emptying of the bladder is accompanied by more or less pain and spasm, and its evacuation is followed by a cramp-like pain ascending along the course of the ureter to the kidney, and radiating to the lower extremity. The patients sleep, as a rule, on the affected side, with the face turned toward the pillow, and it is the habit of many to draw the opposite thigh up over its fellow against the abdomen. The

pain is excited in the early stages by the marital relation, which in nearly all cases becomes intolerable in the advanced stages of the disease.

Other symptoms are associated with the renal pain and the disturbance of the functions of the bladder. Anorexia, nausea, and vomiting are almost always present, especially during the menstrual periods, and as the attacks of vomiting are generally long continued, the vomited matters become stained with bile. Jaundice is not even an uncommon result. Hysterical symptoms form a marked feature of most of the cases. The patients start at the slightest noise, become despondent, cry, and laugh without sufficient cause, and sometimes have well-marked hysterical convulsions followed by a period of unconsciousness. Finally, in the advanced stages of the disease, after years of almost ceaseless pain, when dyspepsia, loss of appetite, nausea and vomiting, torpidity of the liver, constipation of the bowels, and yellowish tinge of the complexion shall have supervened, the general aspect of the subject is that of inanition or starvation, from which, with continually increasing physical and mental sufferings, death puts an end to the roll.

That the pains which I have described as constituting renal tenesmus are referable to ureteritis, beginning in the lower part of the ureter as an extension of cystitis, and are due to spasm of the affected ureter and pelvis of the kidney, appears not only from their situation and character, but also from the following physiological signs and observations.

Tenderness over the kidney on the affected side is usually present. Frequently I find a small area of great sensibility midway between the crest of the ilium and the last rib. There may also be tenderness on pressure in the groin. More important and characteristic than either of these signs is great tenderness at the ureteral orifice, and along that portion of the ureter which lies in the vesico vaginal septum. The slightest pressure upon this part of the anterior vaginal wall on the affected side causes pain, which frequently ascends along the ureter to the groin and kidney. This, together with the sensitiveness of the urethra and the bladder, furnishes an explanation of the dyspareunia which is so commonly present in these cases. Pressure with even a few pledgets of dry cotton also gives rise to pain in the ureter. Looking back over my experience, I recognize these patients as those who were unable to tolerate columning the vagina with dry cotton for displacements of the uterus and ovaries—a practice which I have pursued nearly twenty years.

Paroxysms of renal tenesmus may also be excited in a most striking manner by moderately distending the bladder with warm water. The pressure of the water, when sometimes only a few ounces are used, causes an irresistible desire to urinate, which, if not promptly relieved, is

followed by the pain along the ureter and in the kidney, even in the corresponding hip and lower extremity down to the end of the toes. The patients recognize the pain produced in this way as the symptoms which have been their chief source of suffering. The attacks of renal tenesmus brought on by either of these procedures may last for several hours or days, and are frequently accompanied by great mental excitement and hysterical manifestations. Hence the necessity of caution in adapting these means to the peculiarities of the case.

Corresponding to these clinical facts after a kolpo-uretero-cystotomy is done, we find great sensitiveness and irritability of the bladder and ureter. In the report of my first two cases of pyelitis, I stated that catheterization of the ureter caused but little pain. This is true in a normal ureter, and in some cases of pyelitis with considerable dilatation of the duct; but when pronounced ureteritis exists at or near the vesical orifice of the tube and renal tenesmus is present, the passage of the smallest instrument gives rise to violent paroxysms of pain. In the normal pelvis distention with fluid occasions moderate pain, identical in character with that we are considering, and the quantity of fluid thus injected becomes a measure of its capacity. When renal tenesmus is present, however, the pelvis of the kidney is intolerant of fluid, and the pain beginning before distention is reached may continue for hours. In these cases, therefore, the quantity of water that can be injected is rather a measure of the irritability of the pelvis than of its capacity.

This view of the causation and pathology of renal tenesmus is further strengthened by the results of treatment. As soon as the proper opening is made at the affected orifice of the tube, and the bladder and upper urinary passages are put at rest, coupled with suitable drainage and support of the uterus, the paroxysms become less frequent and soon disappear altogether.

Differentiation from Renal Colic.—The pain of renal colic also depends upon violent contractions of the muscular fibres of the ureter and pelvis of the kidney, and when renal tenesmus is severe there is a close similarity between its paroxysms and those of renal colic. The situation and character of the pains are identical in both, and associated with either there may be a frequent desire to urinate, cramps in the lower extremities, and nausea and vomiting. Both are due to spasm of the muscular fibres of the ureter and pelvis of the kidney; the distinction between them lies in the cause of the contractions. The contractions in renal colic arise from the impaction of a foreign body, usually a calculus in the ureter, causing the urine to collect in and distend the pelvis of the kidney above the seat of obstruction; the contractions which follow are a response to this powerful source of irritation, and the con-

dition of the mucous membrane, whether healthy or diseased, has little to do with their occurrence. In renal tenesmus, however, the irritable condition of the lining membrane, the result of ureteritis, leads to violent contractions of the muscular fibres of the ureter and pelvis from much slighter causes, as, for example, increased tension of the urine during forcible expulsive efforts of the bladder, or, as happens in the bladder, the presence of the urine itself, especially if abnormal, may excite spasmodic contractions. Dependent upon the difference in causation of renal tenesmus and renal colic, each possesses certain distinctive features. An attack of renal colic continues, as a rule, with only short intermissions, until the calculus escapes into the bladder, and the concretion is afterward generally discovered in the urine; the paroxysms also recur at irregular and usually long intervals. The pain of renal tenesmus is less severe and long continued; it comes on more frequently, and the paroxysms, as we have seen, occur several times a day, and often from the most trivial causes. The most important diagnostic feature of renal tenesmus, however, is the facility with which an attack can be excited. When any doubt of the causation of the pain exists, it may be set at rest by making pressure over the ureter where it lies in the vesico-vaginal septum, or by injecting the bladder with warm water in the manner already described. The distinction, thus easily made, is all the more important, because an error in diagnosis, as I have known to occur, may lead the surgeon to perform lumbar nephrotomy and find no stone in the pelvis of the kidney.

Differentiation from Pains in the Ovaries and Tubes.—In the milder cases of renal tenesmus, where the pain is referred to the ureter in one or the other iliac region, and radiates less frequently to the pelvis of the kidney, the pain may be ascribed to ovarian neuralgia or disease of the ovary and Fallopian tube. This error is all the more likely to occur because at times there is no pus in the urine, and hysterical symptoms commonly referred to ovarian irritation may be highly developed; the patient may also describe the pain vaguely as being in the side, as often happens, and her sufferings may be intensified during the menstrual periods. That this error in diagnosis is not a mere theoretical possibility will be seen by the histories of two cases which I will presently report. In one of them the ovaries and tubes were removed a year ago by a distinguished laparotomist of New York; in the second case a Tait's operation was urgently recommended by another. In order to ascertain the cause of the pain the urine should be frequently examined, especially at or about the menstrual periods, the condition of the bladder should be inquired into, and the situation and character of the pain carefully noted; if then any doubt remains, pressure

over the ureter should be tried and the bladder injected with water. The excitation by these means of an attack of renal tenesmus, which the patient recognizes as being identical with the pain she has suffered so long, will at once clear up the diagnosis. May not a more careful and painstaking study of the differentiation between deep pelvic pains, regarded usually as significant of diseases of the ovaries and tubes on the one hand, and the group of symptoms characterizing renal tenesmus on the other, serve to explain the too frequent resort to oöphorectomy as is now believed to be the case by the majority of the profession?

Treatment.—In order to present a clinical picture of our third class of cases, where the inflammation is confined to the bladder and ureter, and is associated with renal tenesmus, I will relate to you the histories of the following cases, together with their treatment:

Case 1.—Mrs. G., æt. 26, a laundress, was admitted into my service in the Woman's Hospital, November 30, 1887. Her symptoms began during her second pregnancy, seven years ago, with pain in the left groin which afterward extended to the corresponding lumbar region. Micturition also became frequent, and she noticed a strong odor and thick deposit in her urine. In 1885, she was under my care for seven weeks. At that time there existed a marked retroversion of the uterus and her urine contained pus. She was treated for the displacement by columning the vagina in the supported knee elbow position, with ordinary dry cotton; but was unable to tolerate the required pressure, and left the hospital without having received any benefit. She was also under treatment for nearly two years in the out-door department of the hospital, but did not improve. In the spring of 1887, both of her ovaries and tubes were removed by a laparotomist of New York City. She entirely recovered from the operation, and during the past year has only menstruated twice. Her sufferings were not relieved, but rather increased, by this operation, especially those relating to the bladder and head.

When she was admitted into the hospital in November last, she had then been suffering from great vesical irritability for seven years. For five years she had been obliged to get up to empty her bladder many times during the night, and during the exacerbations of her symptoms, which occurred at the menstrual periods, she was unable to hold her urine longer than half an hour. The evacuation of the bladder was usually affected by violent and painful contractions or cramps. After the small amount of urine which she could retain was expelled, pain would ascend from the bladder into the left groin and continue for a few minutes or half an hour. At first the pain was confined to the left iliac region, running upward from the inguinal ring along a line to the lumbar region.

At a later period, when her symptoms had increased in severity, it extended to the groin and lumbar region on the opposite side, and finally to the corresponding hip and down the thigh to the knee. Violent and long continued cramps of the muscles of the lower extremities frequently occurred during the paroxysms of pain. The position in bed which she found the most comfortable was on the right side. (In this respect the case is exceptional; most of the patients lie on the affected side.) Her appetite was poor, and during the menstrual period she suffered most from nausea and vomiting.

On palpation, a point was found in the left lumbar region where moderate pressure caused her to cry out with pain. Vaginal examination disclosed great tenderness at the vesical extremity of the ureter. The uterus was now retroflexed instead of retroverted as previously existed, inclined to the left side of the pelvis, and immovable. A mass of exudation could be felt in the posterior cul-de-sac, all legitimate results of the operation she had previously undergone for removal of the ovaries and tubes. The urine contained a small amount of pus; otherwise, was normal.

On December 9, I made an opening in the bladder immediately in front of the orifice of the left ureter. The night after the operation the patient slept soundly, the first time, she declared, in two years. About ten days after the operation the ureter was searched for and found with some difficulty on account of the great tenderness of the bladder at this part. Catheterization and irrigation of the ureter and pelvis of the kidney were painful. The injection of only a drachm of water through the catheter caused violent paroxysms of pain, radiating down the corresponding hip, thigh and leg. Owing to the extreme pain arising from the passage of the catheter, and my failure to find any pus in the pelvis of the kidney, I gave up the practice after a few trials, not deeming it justifiable under the circumstances.

While the patient remained in the hospital her symptoms steadily improved, the paroxysms of renal pain becoming less and less frequent. Owing to the fixation of the uterus, the use of the drainage instrument was less satisfactory in this case than in any I have treated. My utero-vesical drainage support collected the urine fairly well, but, owing to the pain which it occasioned by pressing up the uterus, it could not be worn. A special instrument, made short so as to occupy the vagina in front of the uterus, was tried. This did not cause pain, but collected only a part of the urine. After the patient, however, got accustomed to the presence of the instrument and learned how to manage it better, very good drainage was secured.

The patient left the hospital after having been under treatment about four weeks. I saw her a

few days ago. She was relieved of all her symptoms. She says she is able to do the hard work of a laundress all day, and sleeps soundly at night. When asked if she would prefer to go all her life with incontinence of urine rather than return to her former condition, she answered, "a thousand times."

In the above case the vesical and renal symptoms were well marked, but the hysterical phenomena which, as a rule, form a prominent feature of these cases, was absent. In the following case they were well developed.

Case 2.—Mrs. M., aged 26, was married at 16, and has given birth to three children. Soon after marriage she began to suffer from pain in the urethra, and a frequent desire to urinate following sexual intercourse, and at this time she first noticed a thick deposit in her urine. During her first pregnancy, nine years ago, these symptoms became worse, and in the later months she began to have pain in the right groin radiating to the region of the kidney. These symptoms continued and were aggravated during her subsequent pregnancies. During the early months of her second pregnancy her urine contained blood. For a long time she complained of pain in the head, and suffered from nausea and vomiting during her menstrual periods, at which time all her symptoms were aggravated. In consequence of her sufferings she became nervous and hysterical. Frequently, at the end of a paroxysm of pain in the ureter and kidney, she would have convulsive movements ending in unconsciousness, which continued for half an hour or more. For the relief of the pain she became habituated to the use of morphine and chloral, and took large doses of these drugs. About two years ago an abscess formed in the right iliac region. It opened into the rectum, and the discharge continued for about three months, when it ceased. She recovered from all the symptoms referable to the abscess except a dull, aching pain in the pelvis.

The patient was brought to me from Texas by her family physician, for the purpose of having her ovaries removed. His opinion as to the advisability of the operation had also been strengthened by that of a laparotomist of New York, who diagnosed a pyosalpinx. I first saw her on March 15th.

On palpation a point of tenderness was discovered in the lumbar region over the kidney. Examination of the pelvis in the supported knee-elbow position disclosed the following: The urethra was much thickened, feeling like a hard rounded cord beneath the finger, and the vesico-vaginal septum also seemed indurated and resisting. The uterus was prolapsed and inclined toward the right side. A corresponding displacement of the right ovary existed; it was drawn to the right and imprisoned beneath the uterus. Pressure with the finger on the anterior wall of

the vagina, over the line corresponding to the course of the right ureter, caused severe pain which radiated along the ureter to the kidney and downward to the hip, thigh, knee, leg, and even to the toes. Pressure over the left ureter occasioned little inconvenience. On examining the urine, it was found to contain a moderate quantity of pus.

A few days after the first examination, in order to support the uterus and ovaries and to gradually free them from their confined positions, I commenced columning the vagina with dry cotton in the supported knee-elbow position. I introduced a few pledgets of ordinary cotton, employing very gentle pressure, as is my custom at first in cases where the parts are sensitive. After a few trials this plan of treatment had to be abandoned. The presence of the cotton caused the same group of symptoms which were excited by pressure over the ureter with the fingers.

An attempt was next made to wash out the bladder. When I had injected about three ounces of warm water through a small, soft catheter introduced into the bladder, the patient began to complain of pain. The pain soon became very violent, extending, as usual, along the ureter to the kidney on the right side, and down the thigh to the toes. The paroxysm lasted two or three hours, ending in a hysterical attack followed by a period of unconsciousness.

Failing to benefit my patient by other means, on March 31st, I performed right kolpo-uretero-cystotomy. I was assisted by Dr. J. F. Chauveau, of New York, Dr. Joseph Letcher, of Texas, and my son, Dr. Nathan G. Bozeman, who had charge of the patient after the operation. I made an opening in the bladder about the size of a silver half-dollar, immediately in front of the orifice of the right ureter. The vesical wall was found much thickened and the cavity of the bladder contracted. A utero-vesical drainage support was introduced into the vagina; it collects the urine, and by its use the patient is kept almost perfectly dry.

Since the operation there has been a marked improvement in the patient's condition. She is now entirely free from the attacks of renal pain, is able to sleep all night, and has left off the use of opium and chloral. She can sleep on her left side, which she has not been able to do for two years. Her appetite and general condition have improved, and she is able to go out of doors and take exercise. Nausea and vomiting, which had hitherto been constantly present during menstruation were absent at her last period and the exacerbation of her symptoms usual at this time did not occur. Owing to the elevation of the uterus and ovaries by the drainage support even the symptoms referable to these organs have almost disappeared. In short, now, five weeks after the operation, the patient declares she is entirely re-

lieved and wants to return home. She has increased five pounds in weight since the operation. In this case, owing to the marked and rapid improvement in all the symptoms, I decided not to catheterize the affected ureter and kidney, believing this to be unnecessary. The drainage was almost perfect from the beginning.¹

In order to secure the best results in the treatment of diseases of the bladder and upper urinary passages by the operation of kolpo-uretero-cystotomy, the bladder must be kept free from urine. My practice, as previously stated, is to make the opening about the size of a silver half-dollar. My experience has taught me that an opening in the vesico-vaginal septum of this diameter will contract to the size of the index-finger, depending, of course, upon the degree of hypertrophy the structure has undergone.

But this is not all that is necessary to secure free open drainage and physiological rest of the bladder. The posterior wall of the vagina lies in contact with the fistula and tends to obturate the opening. In the recumbent posture, also, the orifice of the vagina is on a plane about an inch and a half higher than the most dependent part of the posterior cul-de-sac. The urine must, therefore, first partly fill the vagina and bladder before it can escape from the body. Furthermore, in unmarried women especially, where the perineum is intact, a small ostium vaginae prevents free egress of the urine. Another cause of retention in cases of fistula was first pointed out by Jobert de Lamballe; to-wit, extreme anteversion of the uterus. Here the fundus being displaced forward, it carries the superior wall of the bladder before it, while at the same time the vesico-uterine junction is drawn backward by the cervix. In this way is produced a fold in the bladder, and if the fistula be situated high up, it is more or less completely occluded. From some of these causes, it is a matter of common observation that patients suffering from fistula are frequently able in the recumbent posture to retain almost all the urine in the bladder and vagina—as in a common cavity, so to speak. It is evident, when great irritability of the bladder is present and the urine is not entirely drained off, spasms of the organ will persist,

¹ The patient continued to improve until May 28th, fifty-eight days after the operation, when she left New York for her home in Texas, having up to this date gained sixteen pounds in weight. The following is an abstract from a letter to me after her four days' travel in the cars:

"Lampasas, Tex., June 8, 1888. . . . Was sick the first day, but after that got along very well. Did not sit up at all. Had my berth down all the way. Found my family quite well, and delighted to see me looking so well. Have felt real strong since I rested from travelling. Have not felt so well for years. Suffer very little pain anywhere. My friends all think it wonderful that I should have improved so much in so short a time. The instrument is working very well, but the drainage is not perfect, some water seeping to stay in the instrument. . . . I can walk now and sit down with perfect ease; can hardly tell I have the instrument on."

July 16. In a letter of this date from the husband of the patient, he says: "My wife is getting along nicely, and says she will be back in September," that is, for the closure of her fistula.

I have performed three more operations for renal tenesmus, now making six in all, with results equally satisfactory, if not more so, than in the two cases here reported.

the tendency to reflux of the urine into the ureters will continue, and the group of renal symptoms and complications which I have described will not be relieved. The case of Mrs. S—, referred to in a previous part of this paper, proves this point in a striking manner. Here kolpo-cystotomy, it will be remembered, had been performed for cystitis five years before, from which only imperfect vesical drainage was secured. But little benefit was derived from the operation, distress about the bladder continued and ureteral and renal complications in the left side developed two or three years afterward. As evidences of the persistence of the spasms and excessive action of the bladder, I found the walls of the latter, five years after the operation, hard, resisting, excessively sensitive under pressure, and about five-eighths of an inch in thickness, with a cavity of scarcely three ounces retaining capacity.

Another and more obvious advantage which follows the use of the drainage instrument is the relief of the discomfort and evil effects of incontinence of urine. It increases the scope of the operation, because without it I would hesitate to open the bladder in all but the graver cases of vesical and renal disease. By its use the patients are made comfortable; they complain of but little inconvenience, and wait with patience until the opening can be closed.

I have made some changes in the drainage instruments since I described them,* the most important of which adapts them for drainage when the patient lies on her side. Drainage is now secured in all positions of the body. At a future opportunity I will give an account of these improvements, and also a modification of the instrument which adapts it to treatment of incontinence of urine in young girls, arising from weakness of the neck of the bladder, together with other practical points resulting from a more thorough study of the subject.

Frequently associated with disease of the bladder and upper urinary passages there are, as we have seen, displacements of the uterus and ovaries. The uterus is generally inclined backward and to one or the other side of the pelvis. The distortion of the bladder near one of the ureteral orifices resulting from the uterine displacement, and in some cases the pressure of the fundus uteri upon the inflamed ureter, tend to keep up the cystitis and to aggravate the ureteral pain. It is therefore important that the uterus and ovaries should be restored to their normal positions. Before the bladder is opened, owing to the tenderness of the urethra and the extreme sensitiveness of the ureter on the affected side, the use of a uterine support or pessary, however soft, is impossible, and in most instances even gentle pressure with a few

pledgets of dry cotton cannot be borne. Fortunately, after the opening is made the uterus tends to be pushed forward by the pressure of the abdominal viscera, in order to fill the space formerly occupied by the bladder, and owing to the rapidly diminishing tenderness of the ureter the vagina soon becomes more tolerant of pressure.

In order, therefore, to secure the advantages of elevation and support of the uterus and ovaries in combination with drainage of the bladder, the drainage instrument is made thick and rounded at its upper extremity, where it lies in the posterior cul-de-sac beneath the cervix uteri. As a uterine support, its mode of action is similar to that of the dry cotton column applied in the manner I use it. The instrument lifts up the body of the uterus, stretches the posterior wall of the vagina, and tends to carry the cervix backward. Not resting against the symphysis pubis, as does a Hodge pessary, but conforming to the axis of the lower part of the vagina, and sustained chiefly by the perineum and vaginal walls, it exerts an elastic pressure upon the uterus. The instrument consequently yields during sudden movements of the organ, following jars of the body or expulsive efforts of the abdominal muscles. The mucous membrane of the anterior wall of the vagina is applied closely to the concave upper surface of the drainage support and sinks into the perforations made in it for the passage of the urine. This gives steadiness to the instrument and increases its efficiency as a uterine support. At first the drain sometimes causes discomfort; immediately after the operation it is necessary to use a very small instrument, and exceptionally, as in the case of Mrs. G—, the form of the drain must be modified.

I have found continuous irrigation and drainage to be of great value just after the operation, and my system of intravaginal drainage has been extended to accomplish this. For the perfection of the system in the application of suction I am indebted to my son, Dr. Nathan G. Bozeman, and Dr. William B. Gilmer, who have recently been deeply interested with me in working up the subject of drainage, and have materially contributed to my success by their experimental work. This system of continuous irrigation and drainage is of great practical importance and has a wide range of usefulness in general surgery, but the further consideration of it, together with the several improvements made in my drainage supports will be the basis of a future paper.

In my paper on pyelitis, so frequently alluded to, I explained sufficiently the method of irrigating the kidney. In cases where cystitis and ureteritis associated with renal tenesmus are present, the indications for the employment of this procedure are not so clear as when the inflammation has extended to the pelvis of the kidney. My experience so far tends to show that physiological rest

*American Journal of the Medical Sciences, March and April, 1888, and Transactions of the Ninth International Medical Congress, 1887.

and drainage of the bladder and affected ureter are all that are necessary when the complication of renal tenesmus alone exists. After the extreme sensitiveness of the parts has subsided, however, the passage of the catheter may be found useful for its tonic effect, as is the case in a similar condition of the mucous membrane of the male urethra; but further experience is needed to settle this point.

Now, a few words about the time which should be allowed to elapse before closing an artificial fistula. All thickening of the vesical walls and tenderness about the urethra, bladder, and ureter must have disappeared. From six to twelve months, as a rule, are required to accomplish these results. Of late I have adopted a useful method of determining this point experimentally. I introduce a large cylinder of hard rubber—one of my intra-vaginal dilators—which obturates the fistulous opening and keeps the urine in the bladder. If the patient can wear this instrument for a week or two without the occurrence of any distress in the bladder, the opening may be closed at once and the bladder allowed to take on its normal functions.

MEDICAL PROGRESS.

ANCHORING OF THE BRAIN AND SOME OF ITS CONSEQUENCES.—In regard to this DR. WM. MAC- EWEN, in his Address at the recent annual meeting of the British Medical Association, said: When injury has been inflicted on the surface of the cerebrum, followed by plastic effusion and cicatricial formation, the superficial substance is apt to become soldered to the membranes when these remain intact, which in turn may be soldered to the skull, or in the event of their detachment, the brain may become directly adherent to the bone by means of cicatricial adhesion. Thus the surface of the brain becomes anchored or soldered to its rigid walls. It has no longer the free play within its water bed to expand and contract according to the varying states of the circulation. Each variation produces a dragging of the brain at this spot, and through it the whole hemisphere at least is affected. Any sudden physical effort pulls on the brain, producing a slight shock, a momentary disturbance, just as if the cerebrum had received a blow. Vertigo results. People affected in this way cannot rise up quickly, or perform any sudden motion of the body or head, without experiencing a sensation of giddiness, which sometimes causes them to drop. Consequently, they are often incapacitated from pursuing their usual avocations.

Following upon this, the gray matter of the cortex, immediately surrounding the cicatrix, by

the incessant movement is apt to become unstable and to produce fits. Some cases of traumatic epilepsy are thus caused. Further, if the cortical irritation be continued, encephalitis is occasionally produced, often appearing in a chronic form and long remaining so, though susceptible of being lit up into an acute affection. If the temperature remains high, active interference is apt to induce an extension of the encephalitis. Operation in such cases should be, when possible, postponed. The disregard of this advice has, to my knowledge in one instance, hastened the fatal issue, encephalitis becoming rapidly general. — *British Medical Journal*, August 11, 1888.

INFLUENCE OF PILOCARPINE UPON THE MU- COUS MEMBRANE OF THE TYMPANUM.—At the conclusion of an article on this subject DR. W. KO- SEGARTEN, of Kiel, says: It seems evident to me that injections of pilocarpine also have a decided influence upon the mucous membrane of the middle ear, and therefore in chronic processes of the middle ear, accompanied by affections of the labyrinth, this remedy acts not only upon the internal ear, but that it can also exert a favorable influence upon the middle ear process. By means of returning hyperæmia, which may even cause exudation, there ensues pliability of the sclerosed tissues, and moistening and softening of adhesions, and in this way the unyielding conducting apparatus again becomes more capable of vibrating; where exudations had become deposited, their absorption was brought about, as could be observed in the membrana tympani of a patient. The reason Politzer found the remedy inefficient in these affections was because he discontinued treatment too soon, for in these chronic processes we cannot accomplish anything except by long-continued action. — *Archives of Otolaryngology*, June, 1888.

CHLOROFORM WATER AS A VEHICLE.—UNNA, in *Monatsshefte für Praktische Dermatologie*, says that he has found chloroform water an excellent vehicle for the hypodermatic administration of Fowler's solution and ergotin, as it prevents the decomposition of the solution. It is also useful in giving morphia where a local anæsthetic and counter-irritant effect is desired, as in neuralgias. It is equally valuable in the internal administration of drugs which decompose rapidly. Atropine and bichloride of mercury may also be given in chloroform water. — *Med. News*, June 23, 1888.

ABDOMINAL PAIN.—DR. LAUDER BRUNTON (*Brit. Med. Journ.*, June 2) recommends codeine in half grain doses three times a day, increased to a grain if the patient is not relieved. It does not cause drowsiness nor does it interfere with the digestion. In long-continued enteralgia, not due to organic disease, it has continued to relieve pain for months together.

SATURDAY, OCTOBER 6, 1888.

CONGRESS OF AMERICAN PHYSICIANS AND
SURGEONS.

Our reporter has furnished us with a full report of the doings of the general sessions of this new organization, and of the American Surgical Association, at the recent meeting in Washington. The first general session of the Congress was held at 1 P.M. of Tuesday, September 18, 1888, and was occupied solely with the report of the Executive Committee on plan and purposes of the organization and the By-laws, all of which will be found under the head of Proceedings of Medical Societies in the present number of *THE JOURNAL*.

The second general session was held in the evening of the same day and was occupied chiefly with the subject of "intestinal obstructions." But the papers of Drs. H. H. Smith, T. G. Morton, C. B. Penrose, N. Senn, R. Harvey Reed, and some others, with the discussions thereon, in the Surgical Section of the American Medical Association, last May, and since published in full in *THE JOURNAL*, so fully cover the field of intestinal surgery that we do not find such additional facts or views in our report of this session of the Congress as would justify our using it. The third general session was occupied with the subject of "cerebral localization and its relations to cerebral surgery," a report of which will be found in the present number of *THE JOURNAL*. The fourth and last general session was held on Thursday

evening, Sept. 21, when the President, J. S. Billings, M.D., U. S. A., delivered his Address on "Medical Museums," the most important portions of which were published in *THE JOURNAL* for Sept. 22, ult. Aside from these joint or general meetings in the evening, each of the several associations of specialists held their meetings separately and attended to all their work independently, as in former years.

SEE ON THE TREATMENT OF ANEURISM.

At one of the recent meetings of the Académie de Médecine Dr. Dujardin-Beaumetz read a note on the treatment of aneurism, by PROFESSOR GERMAIN SÉE. The first part of the note relates to the presence of bacilli in aneurism, which is remarked upon as a curious coincidence. The other two parts relate to the methods of the internal treatment of aneurisms.

Professor Sée speaks especially of the treatment of aneurisms by iodide of potassium and antipyrin, the good effects of which are confirmed by Dujardin-Beaumetz. M. Sée shows that the iodide of sodium treatment is theoretical, and has not the good results of treatment by iodide of potassium, which is much superior to iodide of sodium in diseases of the heart and blood-vessels, because in small doses the potash salts, according to Traube, act distinctly on the muscular-motor system, and even on the inhibitory nerves of the cardiac arrest. The potash salts are toxic only when used subcutaneously in large doses. Even in doses of 10 or 15 grams a day, the iodide of potassium is not toxic, and any ill effects must be attributed to the iodine rather than to the potassium.

In regard to the use of antipyrin with iodide of potassium, according to Sée, antipyrin has no bad effect on the heart, but, on the other hand, calms the impulse of the heart, which is generally exaggerated in cases of aneurism, and in this way rather adds to the ease with which coagulation takes place, thus favoring the cure. More than this, antipyrin dissipates the sharp pains, the painful cardiac oppression, and the anginous sensations so frequently associated with aneurism. Dujardin-Beaumetz prefers phenacetin to antipyrin in these cases. It is not so soluble as antipyrin, and must be administered in wafers, but to produce the same analgesic effect as antipyrin one

requires only half the dose. Both Sée and Dujardin-Beaumetz condemn all surgical interference in aneurism of the aorta.

THE NEXT ANNUAL MEETING OF THE AMERICAN MEDICAL ASSOCIATION.

It has been ascertained that, at the time selected for the next annual meeting, *i.e.*, the first Tuesday in June, in Newport, R. I., the chief hotels of that city will not be open for guests, and neither will the summer arrangements for boating excursions be in order. By deferring the meeting until the *last Tuesday* in June all these local difficulties will be obviated, and the State Medical Society of Rhode Island has already taken steps to coöperate cordially with the local committee of arrangements in making the meeting one of the most pleasant and successful ever held. We think the committee of arrangements should not hesitate in making the proposed change in the time for holding the meeting, when it would so obviously add to the comfort of all the parties interested.

EDITORIAL NOTES.

ACETIC ACID AS AN ANTISEPTIC IN OBSTETRICS.—DR. F. ENGELMAN thinks that acetic acid is as much antiseptic as carbolic acid, and has the advantage of being non-injurious, even in a tolerably concentrated form. It has a decidedly styptic effect, which is an additional advantage in midwifery practice, and is very diffusible, penetrating the tissues to a much greater extent than most other antiseptics. Its action on instruments is less prejudicial than that of corrosive sublimate. A pair of forceps may be kept in a 3 per cent. solution of acetic acid for a quarter of an hour without being injured, but an irrigator is liable to injury from prolonged use of acetic acid solutions. After using acetic acid the hands must be washed twice, since soap will not dissolve in the presence of the acid. Engelman generally uses a 3 per cent. solution, though he has used a 5 per cent., which, however, is apt to cause a sensation of smarting in any spot where the surface is broken. In none of the cases in which Engelman used acetic acid was there any abnormal rise of temperature.

LEPROSY TREATMENT IN HAWAII.—It is proposed to establish an efficient hospital, in one of

the most salubrious localities in the Sandwich Islands, for the treatment of leprosy. It is felt by the Government that any attempts at cure must be carried out under the most favorable circumstances, and a physician will probably be engaged who is conversant with and can carry out the treatment advocated by Dr. P. G. Unna, of Hamburg. But so long as the utter indifference to isolation of lepers in the Sandwich Islands continues, any plan of therapeutics must be looked upon as scarcely less than vain. The isolation of lepers is as important to day as it was in the time of Moses. The principles of the Mosaic Code have not been improved upon, and the farther sanitarians get away from them the more they stumble.

MEDICAL LEGISLATION IN NEW ZEALAND.—The new Medical Act Amendment Bill of New Zealand, now under discussion, provides for the creation of a General Council of Medical Education and Registration, to consist of twelve persons. All persons registered in the United Kingdom are to be registerable in New Zealand. Any person assuming a title to which he is not entitled is liable to a fine of £50. Persons representing themselves as registered, but not really so, are liable to the same penalty, as is any person not a registered practitioner, but who practices medicine, surgery or midwifery, using the designation of or representing himself to be a physician, surgeon, doctor, apothecary, professor, specialist, or consultant in medicine, surgery or midwifery.

PUPILLARY CHANGES IN CHRONIC PULMONARY DISEASE are discussed by COMINI in *Annali di Oftalmologia*. He cites histories of nine cases of mydriasis in phthisis. This occurred more frequently on the right side, and coincidently with disease at the apex of the lung on the same side. In some cases it was bilateral. In some cases also the mydriasis was accompanied by photophobia and paresis of accommodation. Rampoldi first described the transitory dilatation of the pupil, and maintained that it was directly connected with temporary aggravation of the symptoms. In Comini's cases there appeared to be no such connection. Rampoldi assigned reflex irritation as the cause, but Comini suggests that the sympathetic may be directly involved in the disease.

ABSENCE OF RIGHT PARIETAL BONE AT BIRTH.—MR. G. WASHINGTON ISAAC records a remark-

able case of a child born without a right parietal bone. Over its site the skin was loose and distended with fluid; palpation produced fluctuation. On pressing the fingers firmly into the margins of the swelling the edges of the surrounding bones could be felt. A month later the site was occupied by bone, except a small circular space about midway between the parietal eminence and the posterior superior angle of the bone. About six weeks after birth this hole filled up. The bone was quite firm, but somewhat nodular, especially over the site of the space the last to disappear. In this case the labor was easy and rapid, and the swelling, which somewhat resembled a caput succedaneum, distinctly increased for three or four days.

PERITONITIS CAUSED BY ROUND WORMS.—SURGEON-MAJOR R. D. MURRAY, of the Indian Medical Service, reports three cases of this kind. As the result of his observations in India he has no doubt that the round worm (*ascaris lumbricoides*) is capable of causing perforation of the bowel, and actually boring its way into the peritoneal cavity. These entozoa are very prevalent in Eastern countries and among the dark races generally, and the mortality caused by them is probably greater than is generally supposed. Surgeon-Major Murray says that in times of cholera they are frequently a predisposing cause of the disease.

CREMATION IN ITALY.—The Italian Government, which has done a good deal towards encouraging cremation, has recently applied the principle of protection to dead bodies imported for cremation. Cremation is illegal in France. Not long since a Mr. Morin left instructions that his body should be taken from Paris to Milan, and cremated. The cremation cost about \$3.75, but the Italian Custom House levied \$70 duty on the body when it entered the country, and the same amount as export duty on the ashes when they were taken back to France.

THE LONDON SANITARY PROTECTIVE ASSOCIATION, of which the Duke of Argyll is President, is a society the objects of which are to provide its members, at moderate cost, with such advice and supervision as shall ensure the proper sanitary condition of their own dwellings. The Association has no capital stock, and cannot be used for purposes of profit.

YELLOW FEVER.—Owing to cooler weather the prevalence of the fever in Jacksonville is declining, and much less alarm is felt throughout the South. Light frost has occurred in Tennessee, and snow in some parts of Virginia, and quarantine has been relaxed or discontinued in many places. The whole number of cases reported in Jacksonville, Fla., to Oct. 1st, is 2,725, and the number of deaths 263.

TANNIN IN PHTHISIS.—DR. DE VITI DEMARCO, of Otranto, has successfully used tannin for reducing the temperature of phthisis, and finds that it sometimes has a beneficial effect on the course of the disease. He gives the tannin in the form of a pill, every two hours, each pill containing gr. 7.5 of tannin and gr. 0.25 of creasote. Long-continued use of the tannin seems to produce no unpleasant symptoms.

M. CHEVREUL completed his 102d year on August 25. Though he is suffering from no special complaint, he has become so infirm that he is obliged to pass the greater part of his time in bed. He has not been able to attend the meetings of the Institute for more than three months.

THE PROFESSIONAL DISINFECTOR has appeared in some of the European cities. One in London, a Mr. W. G. Lacy, advertises that he is employed by leading London physicians, and has a private carriage for removing infectious cases without publicity.

THE INTERMITTENT GALVANIC CURRENT is said by Dr. J. R. Seymour to be efficacious in case of sting by the physalia (Portuguese Man-of-War). Perhaps it might be efficacious also in other cases of poisonous and painful sting.

SOCIETY PROCEEDINGS.

Congress of American Physicians and Surgeons.

The first Triennial Meeting of the Congress, held in Washington, September 18, 19 and 20, 1888.

FIRST SESSION—TUESDAY.

The meeting to receive the report of the Executive Committee and for organization was held at 1 P.M. Tuesday, in the Grand Army Building.

The meeting was called to order by DR. WILLIAM PEPPER, Chairman of the Executive Committee, who spoke as follows:

On behalf of the Executive Committee I have to announce the manner in which we have discharged our responsible duty. The present meeting is the result of prolonged deliberation which began to take shape more than four years ago, before the attention of the medical profession became occupied with preparation for the meeting of the International Medical Congress, but all action was deferred in order that there should not be the semblance of interference with that important meeting. This delay has served to render more conspicuous the necessity for this organization.

In order to produce the best scientific results, it is essential that the numbers in attendance shall be reasonably limited and that, as far as possible, the same men shall attend successive meetings, securing a continuity of intellectual life and activity. A large proportion of those interested in the development of such an organization are, as I am myself, warmly attached to the American Medical Association, and determined to exert their influence to maintain and promote the success of that great National organization.

Your Committee ventures to hope that their provisions will meet the unanimous approval of the Congress. We have recommended that the sessions shall be triennial. We have jealously guarded against the admission of parliamentary business, as the functions of the organization are designed to be absolutely or exclusively scientific. We have also guarded the independent sovereignty of each participating Society.

Lastly, the Executive Committee has reached the conclusion that the selection of the President of each Congress shall be entrusted to the Executive Committee then in office. Close study of the conditions of this Congress has led the Committee to feel that if this organization were to have the effect of favoring the multiplication and subdivision of special societies, it would be nothing less than a calamity. We have therefore provided that the admission of new associations shall be secured only by the unanimous vote of the Executive Committee.

It remains only to add that, in exerting the privilege of selecting a President for the first Congress of American Physicians and Surgeons, we feel that we have been guided to the choice of a man whose admirable personal character, whose high attainments, and whose illustrious services in the cause of literature, of science, and of the entire medical profession, mark him as entitled to this great honor. It gives us, therefore, the utmost gratification to present to you our President, Dr. John Shaw Billings, and to announce that the Congress of American Physicians and Surgeons is now duly organized.

President DR. J. S. BILLINGS then took the chair and responded in a brief address.

The *Address of Welcome* was delivered by DR. SAMUEL C. BUSEY, of Washington.

The consideration of the By-laws was next taken up.

1. This organization shall be known as the Congress of American Physicians and Surgeons.

2. It shall be composed of National Associations for the promotion of medical and allied sciences.

3. It shall hold its sessions triennially in the city of Washington, D. C.

4. The officers of the Congress shall be a President, Vice-Presidents, a Secretary, a Treasurer and an Executive Committee.

5. The President shall be elected by the Executive Committee, of which he shall be *ex officio* a member. He shall preside at the sessions of the Congress. He shall deliver an address.

6. The Presidents of the participating societies shall be *ex officio* the Vice-Presidents of the Congress.

7. The Secretary and Treasurer shall be elected by the Executive Committee. They shall be *ex officio* members of the Executive Committee.

8. The Executive Committee shall be composed of one member from each participating society, and said members shall be elected by the various societies at the next annual meetings subsequent to the Congress. It shall be charged with all duties pertaining to the organization of and preparation for the ensuing Congress, including the election of all officers and of a Committee of Arrangements. It shall superintend the publication of the Transactions of the Congress.

9. The expenses of the Congress shall be divided between the participating societies in proportion to their membership.

10. The admission of new associations to participation in the Congress shall be by unanimous vote of the Executive Committee.

These By-laws were unanimously adopted.
Adjourned.

THIRD SESSION.

DR. CHARLES K. MILLS, of Philadelphia, read a paper on

CEREBRAL LOCALIZATION IN ITS PRACTICAL RELATIONS.

In his introductory remarks, the speaker referred to the fact that from the clinical observation of practical physicians sprung the conceptions out of which developed the science and art of cerebral localization. Allusion was made to the discoveries of Bouillaud and of Broca in speech localization; to the announcement by J. Hughlings Jackson in 1864 that certain convolutions superintended the delicate movements of the hand which were under the immediate control of the mind, and to Hitzig's researches having originated from his observing certain ocular movements during galvanization of the heads of his patients. Brief reference was made to the history of Amer-

ican work in localization; to the investigations in 1874 of the New York Society of Neurology and Electrology; to Putnam's discovery that irritation of the white matter beneath definite cortical centres produced movements similar to those caused by irritation of the centres themselves; to the labors of Wood and Ott on the head centres, and to the light thrown by these investigations upon the mechanism of fever and the action of drugs upon different forms of high temperature.

Trephining for cases of insanity, particularly when guided by the rules of localization, was briefly considered. Two of the recent cases of brain operation reported by Bennett and Gould and by MacEwen were cited as possibly opening a new field for surgical interference in insanity, the excision of cortical areas as a method of treatment when certain subjective phenomena such as hallucinations of sight or hearing can be given a local habitation in the brain.

In turning to the surgical aspect of cerebral localization in its practical relations, the author stated that his remarks would be chiefly concerned with questions of diagnosis. The forms of disease in which such diagnosis has been used are intracranial tumors, cysts, fractures, hæmorrhages, abscesses and discharging cortical areas.

In considering the localization of brain tumors, Dr. Mills referred to twenty cases of antopsies occurring in his own personal experience, in about one-half of which the tumors were in surgically accessible areas, and in at least one-fourth of which successful operations might have been performed. He advocated from this experience the excision of old gummata, and also, in special cases, of tubercular growths. The value of localization was shown in cases of fracture where the extent of the unseen damage could not be told by the position and character of the visible lesions.

Of the different forms of intracranial hæmorrhage, subdural, cortical and intracerebral were most amenable to localizing diagnosis. The rules for the local diagnosis of these forms of hæmorrhage were then given. Dr. Mills advocated the performance of trephining in exceptional cases of hæmorrhage into the ganglia and capsules; cases in which symptoms indicated that the bleeding had not broken into and inundated the ventricles. From the sections, the best site for operation in such cases, all things considered, would be in the anterior portion of the first or second temporal gyrus. He favored Hughlings Jackson's suggestion of excising localized cortical areas even when coarse lesions could not be made out, in cases of spasm beginning locally or deliberately.

The inaccessible areas had been narrowed down by the venturesome surgical explorer, and had become reduced to the middle regions of the base and its bordering convolutions, the corpora quadrigemina and the pons oblongata.

The characteristics of localizing symptoms were

described as phenomena of irritation, destruction, instability, pressure, invasion and reflex action. Signal symptoms and the serial order of motor phenomena were discussed. Briefly, in certain regions of the brain an accurate topographical diagnosis could be made with great certainty from positive localizing symptoms. These brain areas include the entire motor zone, in which are embraced the motor or emissive speech area, the region of Broca; the visual area in the cuneus, giving lateral hemianopsia, and the intracerebral visual tracts; possibly, also, the angular gyri and the lateral surface of the occipital lobe. In other regions of the encephalon the topographical diagnosis could be made with sufficient accuracy even for surgical purposes, by the study of the positive symptoms with, in addition, the application of processes of exclusion and successive differentiation. Particular stress was here laid upon the importance of pressure and invasion symptoms. These areas for approximately certain topographical diagnosis include the cerebellum, the prefrontal lobe, the temporal lobe, and even certain cranial nerve districts, as the auditory and facial when the lesion could be localized within the cranium between the superficial origin of the nerves and their entrance into their foramina or canals of exit.

Motor localization had become almost an exact science. The latest physiological research bearing upon the subdivision of the motor area, and the light thrown upon the question by surgical operations, were discussed. It was held to be imperative for the neurologist and surgeon to have exact knowledge, not only of the anterior and the posterior limits, but also of horizontal subdivisions of the motor zone.

The old method of dividing the motor zone into three elliptical or circular areas, from above downward, was considered insufficient; but the neurologist should be able to locate for the surgeon, from a study of motor phenomena, at least seven or eight positions for trephining; these positions being selected by a close study of the initial or signal symptoms, the serial order of movements, and also of the amount and character of the temporary paralysis after the seizure and the method of extension of the persisting palsy.

The view of Ferrier as to the localization of the centre for ocular and head movements in the second frontal gyre was concurred in, and observations were cited in its support; when turning of the head and eyes was the starting point of the spasm, this localization was probably indicated. The fact that cortical oculo-motor palsies were not present as a persistent condition even with definite lesions of the second frontal gyre, was explained by the intimate and peculiar connections of the oculo-motor nuclei at the base; they do not persist for the same reason that paralysis in the upper distribution of the facial nerve is so seldom

permanent. He believed that there was a special centre for the orbicularis palpebrarum movements, probably below and adjacent to the oculo-motor centre.

Dwelling upon the sources of error in motor localization, the question of reflex spasm, of unilateral convulsions due to uræmia, lead, and other toxic agents, and to hysteria and hysterio-epilepsy, were briefly discussed. Sufficient diagnostic difficulties are still present to make it important in the light of the tremendous impetus towards operation, to carefully examine all questions of differential diagnosis. In certain spasmodic affections, the resemblance between those clearly of reflex origin and those as demonstrably central, were very striking. Trigeminal epilepsy, whether dural, facial, dental, nasal, pharyngeal, laryngeal, or of whatever local origin, might cause unilateral convulsions, or even mono spasm. Dural epilepsies are especially worthy of attention, as shown by the researches of Dupuy, Burdon-Sanderson, Brown-Sequard, the New York Society of Neurology and Electrology, Duret, Boche Fontaine, and François Franck. Franck has made a careful comparison and contrast of cortical epilepsies with those which are reflex and toxic, including those which are due to irritative lesions of the dura mater.

The author referred to five cases in his own experience in which operations had been performed for epilepsies apparently reflex in character: two in which spicules of bone had been removed from the dura mater, one in which an old inflammatory lesion of the membranes and cortex from traumatism, was present, and two in which scalp cicatrices were removed. While fearing, with Franck, that we were not always able to make a trenchant separation between reflex and cortical epilepsies, some points of separation were indicated. True Jacksonian epilepsy, Dr. Mills believed, was sometimes reflex in origin, that is, that it was established by intense, persistent peripheral irritation; and even after the irritation had been removed, the cortical discharge continued; herein perhaps lays the explanation of Jacksonian spasm without coarse lesion; and herein also, perhaps, was to be found the justification for the excision of cortical discharging areas. The author referred to a case in which epilepsy clearly of Jacksonian type was just as clearly due to a fibroma involving a nerve trunk on the palmar surface of the hand, and in which the patient was cured by removal of the growth.

With reference to sensorial localization, cutaneous and muscular, the views of Horsley and Schäfer with reference to the limbic lobe were accepted in part. The speaker believed that the evidence was becoming stronger every day in favor of the existence of a zone for the sensations of touch, pain and temperature separate from cortical motor areas. Collections of cases, such as those of Starr,

Petrina, and others, which were supposed to indicate that the sensory areas coincide largely with those of motion, were not regarded as overcoming the positive evidence of decided destructive lesions of the cortical motor zone without any sensory disturbance. From a study of his personal cases, he had concluded that they did not support the doctrine that the motor and sensory areas coincide. Notes of these cases were given, and also cases from other reporters. He believed, with Bechterew, that the loss of sensation in animals who have had the motor area destroyed, was apparent and not real. Some light had been thrown upon this disputed question by careful examination of patients after operation, particularly when certain definite dural areas had been clearly excised. Reference was made to the cases of Horsley, Weir and Seguin, Lloyd and Deaver, and others. The speaker believed that these observations and experiments pointed clearly to the theory that the motor zones were motor alone in function. His view was, the region for general sensation, including touch, pain, temperature, and perhaps pressure, location and muscular sense, could be divided into special areas for the various distinct portions of the body, and that these centres lay alongside and had close anatomical and morphological relations with corresponding motor centres, but that they were not identical with them. He located these sensory areas in the gyrus fornicatus, the hippocampal gyre, the precuneus, and the lateral postero-parietal region.

The practical conclusion was that the neurologist and surgeon must depend upon motor symptoms alone in fixing the site for operation in cases where the motor lesions were definite. When positive sensory symptoms were present they might sometimes serve to aid in locating more exactly the position for operation, but the data were not sufficient for positive reliance. The question of morphological peculiarities of the human brain was briefly alluded to as having some practical bearing upon the subject under discussion. The position of the so-called angular gyre and aberrations in the parieto-occipital region, were more particularly discussed. Even the fissure of Sylvius, the central and parieto-occipital fissures sometimes present considerable variation, but, as a rule, such aberrations were not confusing in operating on the motor region after the methods of Broca, Thane, and others.

DR. ROSWELL PARK, of Buffalo, N. Y., read a paper on

CEREBRAL LOCALIZATION IN ITS SURGICAL RELATIONS.

The following is an abstract:

Cerebral Topographical Anatomy.—The areas which most concern the surgeon are those which cluster around the fissure of Rolando. A few bony prominences deserve attention is this con-

nection; that at the point of the nose, known as the glabella; the external occipital protuberance, known also as the inion; the point of the cervix half-way between these two, the bregma; the external angle of the orbit, the tip of the mastoid process, and the lower border of the alveolar process of the upper jaw. The fissure of Rolando has its upper end about 5 centimetres back of the bregma, but does not run quite in the middle line, its lower end lies about $\frac{1}{2}$ centimetre behind the auricular-bregmatic line and a little above an imaginary line projected backward from the superciliary ridge, thus the lower end of this fissure will be found about 6 centimetres above and a little behind the external auditory canal, or about an inch behind the bifurcation of the fissure of Sylvius. In regard to the convolutions, it must be stated that lesions of the dura-mater overlying motor areas are not always to be distinguished from lesions in the cortex beneath. It is enough for the surgeon that a lesion of some kind can be located with reasonable accuracy. It matters not whether this is an old, irritative lesion; an acute suppurative process between the bone and the brain, or an abscess or tumor of the brain itself. The indication for exploration is just as strong in either case.

When and Where can one Trephine with Safety.

—The safest rule is to first apply the trephine over those areas which do not overlie large vascular channels. Afterward the opening may be extended in any direction and to any required extent. The greatest hesitation is with regard to opening one of the sinuses. Two dangers attend such an accident, one fatal air embolism, the other profuse hæmorrhage. The former danger is almost a theoretical one, and the other may be overcome by plugging the sinus or closing the wound with a fine needle and suture.

Cerebral and Cerebellar Abscess.—Bergmann has shown that abscess of the brain has but one result—death—and that the surgeon's knife offers the only relief. So far as we know there is no such thing as idiopathic abscess of the brain. It is always the result of some external wound of the head or some extension from diseased surrounding bone. The only exceptions to this statement are to be found in the case of pyæmic or tuberculous abscess. The symptoms of deep brain abscess may be divided into three groups, according to causes. 1. Those which are inseparable from indications of suppuration. Such are those disturbances which may follow any deep-seated foreign body. 2. Symptoms of increased intra-cranial pressure and of disturbed relations. 3. Special symptoms by which the locality of the disturbance may be ascertained. So long as the gray matter is undestroyed, the collection of pus may assume large dimensions and still no intense motor symptoms appear. Local elevation of temperature over the abscess is a symptom of importance when

present, but its absence need not negative a diagnosis if made on other grounds. Wernicke has stated that there is a peculiar disturbance of speech which points to a lesion of the temporal region. This is the confusion of correct with incorrect words. In the general diagnosis of cerebral abscess it is to be remembered that there usually is a latent period which may continue for an indefinite period. The stage of active symptoms is usually ushered in by more or less headache, and slight rise in temperature. Local or motor symptoms can only be expected when the abscess is in the motor area of the brain.

In operating for abscess of the brain, operators until recently have satisfied themselves with incising the dura and doing nothing more. With the introduction of aspirating methods the hollow needle came to be used for brain exploration. The dangers of this procedure are certainly small. The danger of hæmorrhage has been overestimated. A temporary tampon will control deep hæmorrhage, while in bleeding from the pia-mater the vessels may be secured with ligatures or serrafius. In brain abscess consequent upon middle-ear disease, the best point to trephine, according to Bergmann, is above and behind the ear. Macewen proposes a second counter-opening on a level with the floor of the abscess.

Brain Tumors.—The principal features of these growths which produce symptoms are location, size, character, rapidity and manner of growth, and extent to which they affect surrounding brain tissue. Considered in their surgical relations we may, with Bergmann, divide them into (a) the circumscribed, or encapsulated, and (b) the infiltrated, or diffuse, around which, as a rule, there is a zone of softening. A third class may be mentioned, *i. e.*, those growing from the interior of the cranium, from the bone or dura.

If a reasonably satisfactory diagnosis can be made it must be indeed an extensive growth of the cranial vault which shall contraindicate operation. The question of what and how many brain tumors are operable has been best answered by White. He found in one hundred brain tumors met with in the dead-room of Guy's Hospital, that only nine could have been removed—one tuberculous nodule, four sarcomas, two undetermined tumors, one cyst, and one myxoma. Nine per cent. could have been attacked, providing a fairly accurate diagnosis had been made. Of these nine tumors, five were located in the cerebellum, one in the frontal lobe, and one in the extremity of the occipital. It is doubtful whether these seven could have been recognized accurately enough during life to justify operation, while the myxoma was impossible to diagnose. It is thus seen that by no means all tumors which can be diagnosed can be deemed suitable for operation.

Operation for Intra-cranial Tumors.—The head should be shaved two or three days before opera-

tion, washed with green soap and ether, and antiseptic compresses applied. Chloroform should be, as a rule, the anæsthetic, on account of its contracting influence on the vessels of the brain. Morphia, hypodermically, and ergot may be resorted to for the same purpose. The author suggested that after localizing the lesion, a small, disinfected, headless tack be driven through the scalp into the bone at the point determined upon. After the dissection of the external flap this will point out accurately the point to be first attacked.

In order to prevent hæmorrhage, the author had found a spray antipyrin solution (1:40) of service. The semi-lunar flap is the proper-shaped one to raise. Its apex should be in such a position as to allow of drainage with the patient on his back. The periosteum should preferably be raised with the flap. The use of the trephine is preferable to the hammer and chisel. Since Macewen has taught us how to preserve the fragments of bone and restore them to their place, his method has been widely tried and universally commended. The dura mater should be incised around a large part of the area at a distance of $\frac{1}{8}$ to $\frac{1}{4}$ inch from the edge of the bone. The appearance of the dura is sometimes a guide to trouble beneath. In recent cases it is sometimes highly vascular; in old cases it may be yellowish or discolored. Wherever adherent it should be freely excised. Horsley claims that marked protrusion of the dura indicates pathological intra-cranial tension. The color of the brain should be noted, remembering that the cerebellum has normally a different appearance from the cerebrum. Sometimes where there is uncertainty as to which convolution is the desired one, the battery may be employed. Where no indication of lesion is found, further exploration may be conducted with a small aspirating needle or a blunt probe.

Should a tumor be discovered the incisions for its removal should be made perpendicularly to the cortex, for the purpose of avoiding hæmorrhage and division of the conducting fibres. Removal of a layer of cortex whether normal or abnormal, does not leave, as one might fear, a prominent gap with vertical sides, since in a short time the depressed portion is made to bulge almost to the level of the intact parts surrounding. In addition the cut edges are slightly everted and if less brain is removed than bone the edges are extended into the opening in the skull; thus there is a continual normal tendency to hernia, but Bergmann and others have shown that this tendency to hernia-cerebri is in inverse ratio to the area of bone removed. Experience has taught that it is wise to remove brain tissue to an extent greater than was at first considered justifiable. In all operations for epilepsy the portions of cortex nearest the evident lesion should be freely removed.

The matter of drainage must be determined according to the circumstances of the case. An

abscess must be drained as long as pus is discharged. After the antiseptic removal of a tumor the cavity should seldom be drained for more than twenty-four hours. The provision for drainage may be removed on the second day, and the wound dressed with reasonable pressure over the flap. Exudation naturally collecting in this cavity will be retained, and will give rise to some pain and disturbance, but so long as the symptoms from this are not severe the wound may be left with confidence that the fluid will be reabsorbed and that the pressure will be the best check to protrusion.

Dangers of the Operation.—The principal immediate dangers are two: hæmorrhage and œdema. Hæmorrhage from the pia or from the brain substance is usually readily controlled, but disastrous hæmorrhage may occur from unexpected sources. When there is bleeding a temporary tampon of iodoform gauze may be applied. The dural and skin flaps are laid over this and an absorbent dressing applied. At the end of forty-eight hours this may be removed and sutures inserted.

The second danger, that of acute brain œdema, may be brought about either by increase of intra-arterial pressure, or by obstruction of the venous channels of escape. Under this accumulation the brain becomes more sodden. Removal of a portion of the cranium is virtually a diminution of the pressure normally exercised on its contents, and is often followed by reaction with production of excess of fluid.

The author had collected reports of 63 cases which were presented in summary and in tabular form. Seventeen of these terminated fatally, although only 5 of these deaths could properly be attributed to the operation. Fifteen of the cases were abscesses, subdural or subcortical. In 11 cases the lesion was a tumor, exclusive of tubercular nodules. Of cysts, properly speaking, there were 12. The 25 other cases were of a miscellaneous nature. In three cases the true character of the lesion was not revealed during the operation, and was only discovered at the autopsy. In two cases in which no palpable or visible lesion was discovered at the time of operating, the symptoms which led to the performance of the operation were nevertheless relieved, though nothing but careful exploration was practiced.

Of the 63 operations, 17 were performed by American surgeons. Those who have themselves operated more than once are, with the number of their operations: Macewen, 12; Horsley, 11; Bergmann, 4; Weir, 3; Keen, 3; and Parks, 3.

DR. DAVID FERRIER said that he took special pride and satisfaction in the fact that this subject had been assigned such an important place in this great gathering of the profession in this country. He had long cherished the idea that the determination of the functions of the brain would in time

lead to the successful treatment by surgery of some of the most distressing ailments of our fellow creatures. When he first broached the possibility of this he received little encouragement, but now cerebral surgery had become a distinct branch of the art of surgery. There is a great future for cerebral surgery. We must, however, be cautious, lest we do things which our better judgment and larger experience may not consider altogether justifiable. While there have been many successes, yet there had been some failures. He alluded more particularly to cases of Jacksonian epilepsy. The discharging lesion has been removed in many of these cases without permanent cure. Care must also be taken that in curing one affliction we do not induce a greater evil. There is yet much to be learned in regard to the functions of the brain and in regard to the diagnosis of cerebral disease.

MR. VICTOR HORSLEY described briefly the results of his experiments upon the motor region. He believed that here three functions were clearly represented. 1. The representation of the so-called tactile sense; 2. representative of the so-called motor sense; and 3. the great representative of movement. It is found that morphologically the large cells in the fourth layer are concerned in the representation of movement, and he could not understand why we should not allot to the small cells in the upper layer the representation of sensation. He had divided the motor region into minute areas and studied the effect of irritation of these separate areas. He had found that the representation for any part was not limited to one minute portion of the brain, but that there was a focal point where it was strongest, and then it gradually diminished as we passed outside. In his different experiments he had met with certain points of difference. These were attributable to the employment of different species of monkeys. He now uses only the bonnet monkey, and for all practical surgical purposes the results are perfectly applicable to man.

Experiments performed during the past summer had enabled him to prove that the convulsions of so-called Jacksonian epilepsy were solely due to the cortex, and not at all dependent upon the spinal cord or upon the bulbar spinal system.

In cerebral surgery we practice simply the ordinary rules of surgery. In cutting out the bone, a 1-inch trephine should be first used to determine the thickness of the skull. The surgical engine may then be used to cut almost through the portion of bone to be removed. The bone may then be removed with strong forceps. The dura mater should be first separated. If nothing is found and the operation is an exploratory one, the dura mater should be opened. If we purpose to use Faradism for the recognition of certain areas, it is important that the ordinary antiseptic solutions should not be applied to the brain, for they tend

to prevent the response to the electric current.

Parenchymatous hæmorrhage may be prevented by the use of morphia. The ligature must be always applied if possible; never pack the wound. In regard to the recurrence of epilepsy in operations performed for the relief of this affection, he considered that the recurrence was due to incomplete operation. In those cases in which he had removed to his own satisfaction not only the lesion but the surrounding brain substance for at least 1 centimetre, there had been no return. He agreed with the previous speaker that there was danger of doing too much in certain cases.

DR. M. ALLEN STARR, of New York, said:—It is evident from the statements just made that cerebral surgery has a great future, but is dependent on neurology for its guide. The burden of responsibility for future progress rests upon physicians, for diagnosis must precede operation. The great discoveries in cerebral localization made in the past, have been reached by means of the collection and analysis of large numbers of cases of localized disease in man, rather than through physiological experiment. Future advance must be in the same line. Hence the importance, too much overlooked in this country, of recording carefully every case of cerebral disease. And to be properly recorded it must be carefully examined. This is especially necessary in the cases of disturbances of speech.

The history of aphasia presents three epochs: First, that of Broca, in which the fact was established that lesions of the third frontal convolution on the left hemisphere produce aphasia. Secondly, that of Wernicke, in which a distinction between sensory and motor aphasia was drawn, and the former was shown, in a few cases, to be due to lesion of the first temporal convolution. Thirdly, that of Charcot, in which the four mental elements of speech were carefully separated. Charcot says, "A word is a complexus; in it we can discover, in persons of education, four distinct elements; the auditory memory picture, by whose means we are able to grasp the sense of words heard; the visual memory picture, which enables us to comprehend the words written or printed; and also two motor elements, the motor memory of articulation, and the motor memory of writing; the first developed by the repetition of movements of the tongue and lips necessary to pronounce a word, the second by the practice of motions of the hand and fingers necessary for writing." Each of these memories being distinct, can be lost. The result is disturbance of speech, whose forms vary. The loss of visual memories produces verbal amnesia and word blindness; the loss of auditory memories causes word deafness; the loss of motor memories of writing results in agraphia; the loss of motor memories of pronunciation produces motor aphasia. Individuals differ largely in the degree of cultivation of each of these mem-

ories, and hence suffer differently when affected by their loss, *e.g.*, the literary man presenting far more symptoms than a common laborer when his memories of things read are lost. Another fact of importance is the independence of speech and thought. Aphasics may retain their musical faculties, and may sing when they can not talk. Thinking, though largely done by the aid of speech, is not dependent upon it. We have memory pictures of the shape, form, sound and odor of objects, independent of their names, and unless these are intact in the brain, the perception of the object does not produce recognition of its nature or use, and does not awaken the memory of its name. The condition termed apoaxia, is found with aphasia in some cases, but not in all.

Turning from clinical distinctions to pathology, the localization of the various memories necessary to speech, was discussed. Motor aphasia is produced by lesions in Broca's centre, or in the tract from that centre to the cranial nerve nuclei. If it is due to lesion in the latter, it is temporary and accompanied by other local symptoms. The situation of the lesion producing motor agraphia is uncertain. Word deafness is due to lesion in the first temporal convolution, and is associated with word blindness when the lesion extends to the supra-marginal convolution and angular gyrus. All the cases of pure sensory aphasia in which the lesion was limited to these parts (41 in number) were collected, and a chart of the brain was shown to support the localization stated. The condition of apoaxia was shown to accompany lesions situated in or beneath the angular gyrus.

The integrity of the connecting tracts between the various memory-centres is also necessary to the act of speech. These can be tested; thus repetition after another, copying, writing at dictation and reading aloud, are acts involving two separate areas and their connecting tract. Lesions of these tracts produce disturbances of speech, some of which Licktheim has described. But cases have not yet been sufficiently well tested to warrant any conclusions. The necessity of careful examination of all cases to detect various defects was dwelt upon, and the speaker closed by indicating how readily accessible to surgical interference the speech areas of the brain are.

DR. W. W. KEEN, of Philadelphia, compared the head cavity to the other cavities of the body. The brain may be considered to be made up of a number of viscera having separate and distinct functions, and each of which has its own physiological signs and symptoms. While we should be careful not to do too much, we should not err in the other direction. The timidity with which the surgeon formerly approached the abdominal cavity was remarkable; the boldness with which we now attack lesions of this cavity, is almost appalling, and the success equally gratifying. This history will be repeated in the case of the brain.

DR. ROBERT F. WEIR, of New York, had, since 1883, operated in ten cases of brain surgery: three times for tumor, three for abscess, twice for hæmorrhage into the cerebrum where there was no external injury to indicate its locality; once for epilepsy, and once for cerebral pain. In the last case the tumor was so deep that there was nothing to indicate its presence after the brain was exposed. It was one and a half inches below the surface. The growth proved to be a sarcoma. The operation was done last November. The patient is still living, but there are signs of a recurrence of the growth.

Bergmann says that operation should not be performed when the patient is in coma, or when the tumor is large. Dr. Keen has removed a tumor weighing over four ounces, with recovery, and Mr. Horsley has removed, with success, a tumor weighing four and a half ounces, from a patient in a state of coma. Sometimes, although no tumor is found, the operation causes disappearance of the symptoms by relieving the pressure. This might be applicable in apoplectic hæmorrhage when the clot could not be removed.

I have gone over the brain to find what parts are accessible to surgical interference. We are able to strip up the longitudinal and lateral sinuses to a considerable extent. The dura-mater may be separated for a considerable distance from the bone. He had been able to raise up the frontal lobes so as to see the anterior clinoid processes, and he had been able to feel the foramen magnum.

American Surgical Association.

Annual Meeting, held in the Main Hall, Grand Army Building, Washington, D. C., September 18, 19, 20, 1888.

(Continued from p. 460.)

TUESDAY, FIRST DAY.—AFTERNOON SESSION.

The Association was called to order at 2 P.M., by PRESIDENT AGNEW.

NICHOLAS SENN, M.D., of Milwaukee, read a paper on

THE RELATION OF MICROÖRGANISMS TO INJURIES AND SURGICAL DISEASES.

The paper was so extensive that in the limited time allotted to its consideration, the author was able to refer to but a few of the points which it contained. At the present time no argument is required to show that many special conditions are due to the presence of bacteria. In regard to the so-called hereditary transmission of disease, the author held that the specific microbes of the specific diseases are transmitted directly from parent to child. In evidence of this he referred to cases of so-called hereditary osteomyelitis in

newly-born infants. In other cases while this same origin may be inferred we have, as yet, no direct evidence that such is the case. In regard to the questions whether or not pathogenic micro-organisms exist in the healthy body, while the results of some observers point in this direction, the results of others are opposed to the existence of pathogenic organisms in the healthy body. The conclusion was that under certain circumstances, pathogenic organisms might be present. There is proof of this in cases in which after accidental injury there is localization of these pathogenic organisms. Acute suppurative infectious osteo-myelitis following slight injury or exposure was cited as an illustration of this fact. This localization is favored by certain anatomical conditions. The antagonism among microorganisms was being considered when the time of the author expired.

DR. ROSWELL PARK, of Buffalo, had done some work in this direction. He had examined pus from fifty-two sources, and presented a table showing the number of cases in which pyogenic bacteria were found.

He had also prepared culture media with various antiseptics in different proportions, including carbolic acid, iodoform, iodine naphthaline, hydro-naphthal, resorcin, trichlorophenol, creolin sulpho-carbolate of soda, boric acid, perchloride of iron, antipyrin, antifebrin and quinine. Almost the only one of these antiseptic jellies as thus prepared which has presented all growths was hydro-naphthol, 1:100. This shows that hydro-naphthol can be relied upon as antiseptic. Many of the bacteria grow freely on iodoform jelly 1:100. Those which grew abundantly on iodoform jelly grow slightly on oxide of zinc jelly 1:100. Oxide of zinc was considered a better solid antiseptic than iodoform. The author thought that our present knowledge permitted us to associate certain bacterial forms with definite pathological lesions. In conclusion he presented the report of a case of abscess of the face in which he found the micrococcus tetragens. So far as he knew this microorganism had never before been found in phlegmon in man.

DR. WM. H. CARMALT, of New Haven, remarked that there was only one point to which he wished to refer, that was reference to the alleged microbic origin of tumor. A great deal has been said in regard to the microbic origin of cancers and other tumors. He thought that the division of Virchow's class of granulomas into a class of tumors by themselves, known as infectious tumors, is correct. This class includes tubercle, syphilomes, lepra, lupus, actinomycosis and myelitis. These growths should be taken out of the class of tumors and assigned to a class by themselves. He had been unable to convince himself that tumors proper have a bacteriological origin.

DR. N. SENN in concluding the discussion, said that the diseases enumerated in his paper included only those in which the specific cause had been isolated, cultivated outside of the human body, and in which the injection of this culture produce identical lesions. When these three things are done we have furnished positive proof that the disease is due to specific germs. Another class of diseases had been alluded to in the paper in which there was reason to believe from analogy that the affection was due to specific germs, although the three conditions above referred to had not, as yet, been fulfilled. So far no one had been able to show that the supposed bacillus of syphilis was the specific bacillus. That it is a specific disease cannot be doubted; that it is due to a microbe cannot be doubted, but to establish this positively, experimenters must do what Koch did before he announced the specific origin of tuberculosis.

He was firmly convinced from his observations that tumors, in the true sense of the word, were not due to microbes. He had made tumor implantations for many years in animals and in justifiable cases in man, both close to the original seat of disease and at remote points, without obtaining the least evidence of the *microbic origin* of disease.

DR. W. W. KEEN, of Philadelphia, then read a paper entitled

THREE CASES OF BRAIN SURGERY.

The first case was one of removal of a large tumor from the brain; the second trephining for old depressed fracture followed by epilepsy; with removal of underlying brain substance; the third was the removal of the cerebral motor centre for the left wrist and hand for epilepsy. The three patients were presented.

(To be concluded.)

FOREIGN CORRESPONDENCE.

LETTER FROM PARIS.

(FROM OUR OWN CORRESPONDENT.)

Abortive Treatment of Gonorrhœa—Mortuary Statistics—Artificial Suppression of Menstruation—Treatment of Retained Placenta—Cataract of Glass-makers.

Dr. Mauriac, in a note on the treatment of gonorrhœa, has summarized his conclusions as follows: 1. The abortive treatment is indicated and has some chance of succeeding in acute gonorrhœa only during the first hours of its outset. 2. All the attempts to cut short an attack of gonorrhœa during its period of progression and when it reaches its height are useless or dangerous, one obtains only delusive cures. 3. The antiseptic practice at once (*d'emblée*), suggested by the mi-

crobian theory of gonorrhœa, has till now produced only delusive results. 4. It is indispensable to submit acute gonorrhœa to an antiphlogistic treatment until the almost complete disappearance of the most inflammatory phenomena. It must proceed to the proper stage of maturity before any repressive medication should be had recourse to. 5. This latter gives decisive and durable results only in the involutive phasis of the specific catarrh. 6. The agents of repressive medication are copaiba and cubebs internally, the sulphate of zinc in injections. 7. The balsam should be given first; it sometimes of itself produces a definitive cure. In the greater number of cases, while continuing its use, astringent injections may be resorted to. 8. The duration of the repressive medication should be short. Should it not soon give the results expected of it, it must be given up and antiphlogistics resorted to. 9. It is by the antiphlogistic medication that the treatment of acute gonorrhœa imperfectly cured should be commenced. These cases which return almost incessantly are seldom or never subdued in a definitive manner.

Every year the Registrar of the Morgue furnishes a report of the number of bodies deposited there, the cause of death, the kind of death, etc. In 1886 the Morgue had received 932 bodies, in 1887 928. The figure 928 is decomposed as follows: Men, 545; women, 172; newborn infants, human débris, 153. In 1886 there were 329 suicides, of which there were 259 men, 170 women; 180 homicides, 60 men, 120 women; 89 accidents, 70 men, 19 women; 74 sudden deaths, 46 men, 28 women; 360 from unknown causes, 300 men, 60 women. In 1887 there were 338 suicides, 265 men, 73 women; 75 homicides, 57 men, 18 women; 90 accidents, 80 men, 10 women; 80 sudden deaths, 50 men, 30 women; 345 from unknown causes, 285 men, 60 women. As regards the kind of death the report gives: Submersions, 398; natural deaths, 70; run over by carriages, 60; railway accidents, 28; other accidents followed by sudden death: 67 falling from a height; 40 from asphyxia; 37 from firearms; 15 from cutting instruments; 20 from poisoning; 8 by hanging; 58 from electric shocks; 5 from homicides by divers arms; 50 from burns; 20 from blows; 20 by criminal abortion; 2 uncertain; 30 from diseases. The month which furnished the greatest number of bodies is the month of May, that which furnished the least is the month of December. As regards suicides, bachelors furnished the largest contingent, then came married persons and, thirdly, widowers.

We do not often hear of the artificial suppression of menstruation being employed as a therapeutic measure. According to a note reproduced in the *Revue Obstétricale et Gynécologique*, Dr. Loewenthal, of Lausanne, relates the history of twenty-three cases in which this measure had

been employed with advantage in chlorosis. The method employed consisted in injections of hot water of the temperature of at least 49° C., with complete rest in bed. In some very rare cases, iced water was employed preferably to hot water. In eighteen cases the remedy was employed for pure chlorosis. The five others comprised two cases of grave hysteria and three of convalescence from exhausting maladies. In these latter the convalescence was shortened. One of the hysterical patients received a marked advantage, and all the chlorotics were cured with surprising rapidity, and without ulterior medication, after from three to five menstrual suppressions. No grave consequences were noted.

In the treatment of retention of the placenta Dr. Pinard, a well-known obstetrician, remarks that it is important, in the first place, to ascertain the condition of the uterus. This may be voluminous, ill-defined, or it may be retracted, consistent. In the first case the retention is caused by inertia, in the second by the premature retraction of the womb. To overcome the inertia of the organ, and to provoke its contractions, Dr. Pinard advises intra-uterine irrigations of very hot water, of a temperature of from 45° to 48° C. They should be practiced with an aseptic liquid and in great abundance (from 3 to 6 litres). After the application of this procedure the author always found the uterus retracted, the placenta detached and expelled. He gives a caution as to the use of the ergot of rye in these cases. Dr. Pinard then studies the retention of the placenta either by the total retraction of the uterus, the maximum of which is at the internal orifice of the cervix, or by the partial retraction of the organ, which then determines the imprisonment of all or a portion of the placenta. This imprisonment may be diagnosed by the hand applied to the abdominal parietes. When the retraction is total the uterus may be felt with its normal form, and when it is incomplete the organ will appear hard, ligneous, but of an irregular form. Authors are divided as to what should be done in such a case. Dr. Pinard is in favor of direct intervention.

In a note in the *Petit Journal de la Santé* on the cataract of glass-makers, the author remarks that a German physician found that of 442 glass-makers aged less than 40, there were 42; that is to say, 9.5 per cent., affected with the commencement of cataract; and of 64 glass-makers aged more than 40 years he found 17, that is, 26.5 per cent., affected with the same malady. This proportion is far above the average. In order to account for the cause of this singular predisposition the author made some researches, and came to the conclusion that the trouble of the crystalline lens is due, on the one hand, to the direct action of the intense heat on the eye, particularly the left eye, which is the most frequently affected; on the other hand, the enormous loss of water caused by

the excessive perspiration under the influence of the heat. It is by this excessive loss of water that may be explained the production of cataract in diabetic subjects.

A. B.

DOMESTIC CORRESPONDENCE.

Surgical Instruments and Case.

Dear Sir:—In surgery, the spirit of the times is simplicity with efficiency. Economy in means as well as time the busy practitioner desires, when efficiency is not destroyed by this economy. Instruments to be used by the general practitioner must be neat, practical, easy to comprehend, and constructed with a special consideration for aseptic

sis, the surgeon's bane. These conditions must be observed, and these attributes must be obtained, if the work of the surgeon is crowned with success.

I wish to call the attention of the profession to a little amputating case, so complete in all its appointments and so efficient in the work of minor surgery as to make its possession very desirable. This is a compact case, (made by J. LaF. King, of this city), 7 x 3 x 1 inches, can be carried in the pocket, and yet it contains 2 amputating knives, 1 Liston blade $7\frac{1}{2}$ inches long, with adjustable handles, 1 short knife for circular operations, 1 Hamilton bulldog forceps, 4 artery clamps, 2 serrasins, 1 folding saw frame and handle, adjustable to any angle, 2 $6\frac{1}{2}$ inch saw blades, which can be arranged in handles either for amputation or resection, 1 suture carrier and needle holder, which is the crowning feature of the case. This needle carrier is arranged for wire, gut or silk. A number of sutures can be made with it, some new stitches peculiar to the device not heretofore made, the inventor introduces with the needle. It makes the continuous suture, lock stitch with parallel thread on both sides of wound, a chain stitch, parallel thread on both sides, over and over stitch, ball and glove stitch; but the most important is the interrupted self-limiting suture, a most perfect knot that does not slip, holding the first tie just where you place it, tight or loose, until final knot is made. The carrier is $4\frac{1}{2}$ inches long, with hollow handle for needles and wire, and chambers for three bobbins, carrying about forty yards of silk. The needles have various curves, prick point, cutting edges, and adjustable by screws to any angle, and the whole case is constructed with special aseptic features.

Its compactness, its wide scope of usefulness, its novelty and efficiency, are worthy the surgeon's attention, while the genius displayed in the device of saw handle and needle carrier makes it useful for so many purposes, and the moderate price asked for it by the inventor makes it desirable to possess it.

The manufacturer has kindly furnished me cuts of the case and needle carrier that better illustrate the instruments than a mere wordy description.

B. M. GRIFFITH, M.D.

Springfield, Ill., Sept, 10, 1888.

Above cut represents instruments nested in case, and same instruments lettered adjusted on cover. Case is 7 x 3 x 1 inches, full morocco, velvet lined.

Carrier, Bobbins exposed. Holes in head show directions needles can be used.

"The Ethics of Marriage."

Dear Sir:—Dr. Ingersoll, in *THE JOURNAL* of Sept. 22, referring to your editorial on "The Ethics of Marriage" (See *JOURNAL*, Sept. 1, 1888), corrects the statement that "New Mexico, New Jersey, South Carolina, Texas, and the District of Columbia, have no laws relating to the punishment of attempts to perform abortion," so far as the same applies to New Jersey. Now, sir, to prove to you that Texas is not entirely oblivious to matters of protection of the health of her inhabitants, and is not lagging in the race of her sister States in regard to the "stringency of her laws," the records of our State courts show that the violator gets a taste of Texas justice.

In confirmation of the above, I beg leave to refer you to the following Articles of the Criminal Laws of Texas, viz.:

Art. 536.—"If any person shall administer to a pregnant woman, with her consent, any drug or medicine, or shall use toward her any violence, or any means whatever, externally or internally applied, and shall thereby procure an abortion, he shall be punished by confinement in the penitentiary not less than two, nor more than five years; if it be done without her consent the punishment shall be doubled."

Art. 537.—"Any person who furnishes the means for procuring an abortion, knowing the purpose intended, is guilty as an accomplice."

Art. 538.—"If the means used fail to procure an abortion, the offender is nevertheless guilty of an attempt to procure an abortion, provided it be shown that such means were calculated to produce that result, and shall be punished by fine not less than one hundred, nor more than one thousand dollars."

Art. 539.—"If the death of the mother be occasioned by an abortion so produced, or by an attempt to effect the same, it is murder."

Thus, Mr. Editor, you will see that Texas, also, does not "wink" at that "too frequent crime." In justice to the name of our great State, you will please give the above a place in *THE JOURNAL*.

W. W. REEVES, M.D.

Wills Point, Texas, Sept. 28, 1888.

Dr. Ord and the "Family Doctor."

Dear Sir:—In common professional courtesy I cannot allow the remarks of your occasional correspondent (London Letter, *JOURNAL*, Sept. 22) on Dr. Ord to pass without comment. Dr. Ord is a man whose work and worth are universally recognized, and a life-long devotion to the highest interests of the profession should, in reputable journals at least, protect him from baseless attacks.

The article in question, in the "Family Doctor," bears internal evidence of composition by some

one who had obtained such general and specific information as is readily available about prominent physicians, but the ignorance of the writer and the lack of intimate personal knowledge are shown by the fact that Dr. Ord's address is given at a house from which he had moved several years ago!

During his stay in this country last year Dr. Ord was ill, and had indeed reasons of an acutely personal nature for not attending the meetings of the Medical Section of the Congress.

Yours very truly,

WM. OSLER, M.D.

1502 Walnut St., Phila., Sept. 29, 1888.

BOOK REVIEWS.

THE BEST SURGICAL DRESSING. How to prepare it and how to use it. With a consideration of BEACH'S PRINCIPLE OF BULLET-WOUND TREATMENT. By OTIS K. NEWELL, M.D., etc. Sm. 8vo, pp. 170. Boston: Cupples and Hurd. Chicago: W. T. Keener.

After a short introduction in regard to the use of iodoform in surgery, Dr. Newell gives a translation of Miculicz's paper on the "Use of Iodoform in Surgery," which appeared in the *Wiener Klinik* in 1882. Most American readers are probably familiar with the general conclusions of Miculicz, though this is the first time, we believe, that the paper has appeared in full in English. In the six years since Miculicz wrote his paper, iodoform has found its legitimate place in surgery, and there are few that will now deny its value.

The second part of the book deals with Beach's principle of bullet-wound treatment. Surgeons are pretty well agreed as to the proper treatment of bullet-wounds of the chest and abdomen. But in other cases, says Dr. Newell, they seem, as a rule, to disregard the following principle of bullet-wound treatment: "Never disturb a bullet-wound unless there are positive indications of the necessity of so doing." Or in the words of Roswell Park: "The injury which a bullet may inflict is done by it as it passes in its courses; any subsequent harm usually comes from unwarranted interference." The ball, on account of the heat generated by its passage out of the weapon and through the air, may easily enter the body in an aseptic condition, and when thus imbedded in the tissues may be an innocuous and inoffensive substance. In a general way it may be said that probing for a bullet under these conditions, or at all when one is not prepared to operate, is not good surgery. This expresses, in a general way, what Dr. Newell calls Dr. Beach's principle of bullet-wound treat-

ment. A number of illustrative cases are given to show the practical working of the principle in practice.

MISCELLANEOUS.

NEW EDITION.—J. B. Lippincott Company, Philadelphia, announces that a new edition of the *United States Dispensatory* is now being bound, and will be ready in a few days. The revision has been thorough, and not merely the addition of a supplement. More than one third of the book, or nearly eight hundred pages, is entirely new matter, while the whole work has been most carefully rewritten. The National Formulary has been incorporated.

CLINICO-PATHOLOGICAL SOCIETY, OF WASHINGTON, D. C.—The officers of the Clinico-Pathological Society of Washington, D. C., which was organized in the early part of last winter, are as follows:

President, G. W. Johnston, M.D.
1st Vice-President, H. L. E. Johnson, M.D.
2d Vice-President, H. B. Deale, M.D.
Treasurer, C. W. Richardson, M.D.
Secretary, D. K. Shute, M.D.

A **SANITARY CONVENTION** will be held at Hastings, Mich., under the auspices of the State Board of Health, on Monday and Tuesday, December 3 and 4, 1888.

There will be sessions the first day at 2:30 P.M. and 7:30 P.M.; on the second day at 10 A.M., 2 P.M., and 7:30 P.M. Standard time. At each session of the Convention there will be addresses or papers on subjects of general interest pertaining to public health, each paper to be followed by a discussion of the subject treated.

Officers of the Convention.—President, Hon. D. R. Cook.

Vice Presidents.—Hon. Clement Smith, Hastings; William H. Young, M.D., Nashville; S. C. Rich, M.D., Middleville; Eugene Davenport, Woodland; Norman Latham, Baltimore; H. F. Peckham, M.D., Freeport; A. C. Towne, Milo; Prof. J. W. Roberts, Hastings.

Secretary, A. E. Kenaston, Hastings.

The admission to all sessions of this Convention will be free, and the ladies are cordially and especially invited. The invitation is especially extended to health officers to be present and take part in the discussions.

The objects of the Convention are the presentation of fact, the comparison of views, and the discussion of methods relating to the prevention of sickness and deaths, and the improvement of the conditions of living. This is not a doctor's Convention, but it is for the people generally.

Addresses and Subjects to be Presented and Discussed.—Brief statement of objects of Convention, by Hon. John Avery, President of State Board of Health.

Address by the President of the Convention, Hon. D. R. Cook.

Among the subjects which it is expected will be presented and discussed are the following:

1. The Water-supply of Hastings.
2. Plats of Localities in Hastings.

13. An Address by Prof. Vaughan, of the University. Authors of papers are requested to limit them to twenty minutes. The speakers who lead the discussions are to be allowed ten minutes each, all others five minutes.

The papers are expected to be original contributions, which, when read, are to be considered the property of the Convention, and to be left with the Secretary. Programmes will be issued before the Convention.

Committee from the State Board of Health.—Henry B. Baker, M.D., Lansing.

Local Committee.—Hon. Daniel Striker, Chairman; Hon. Jas. L. Wilkins, Mayor of the City; Dr. D. E. Fuller, City physician; W. L. Wilkins; Dr. A. P. Drake; C. W. Warner, City recorder, Sec. of Committee.

Committee on Finance.—John Bessmer, Dr. Wm. H. Snyder, M. L. Cook.

For further information address A. E. Kenaston, Sec'y., Hastings, Mich.

THE AIR OF COAL MINES.—MR. T. G. NASMYTH, in a report to the Scientific Grants Committee on "The Air of Coal Mines," draws the following conclusions:

From comparison of the state of air in coal mines with that in one-room houses, schools naturally ventilated, and manufactories, it will be admitted that it is wonderfully good. The problem of mine ventilation is a difficult one, but by the use of fans it has been solved to a certain and large extent. It would not be easy, if possible, to ensure that the air of mines would be as pure as the air above ground, as so many causes are coöperating to vitiate mine air—respiration and excretions of men and horses; combustion of powder, oil, and tallow; the exudation of gases peculiar to the various minerals met with in mines; and the decomposition of wood. To keep the products of all these in moderation a large and ever-moving volume of air must pass in and out of the mine. The sectional area of the air shaft would have to be much larger than present uses demand if the impurities were to be reduced to the quantity found in pure air, but the present system might, in my mind, be much improved by attention to some points which have struck me in the present inquiry, and which I now venture to suggest to those concerned.

The miner spends about one-third of each day in the mine, and we may assume that about one-third of his excreta pass into the mine, and there remain as a source of pollution for an indefinite time. Horses are at all times in the mine, and their excreta are constantly polluting the air, and this cannot even partially be avoided. The evil produced by the former might be diminished by the use of some form of earth closet, small coal or coal dust taking the place of earth. The receptacles could be removed daily or weekly, according to circumstances. This proposal may not strike a coal owner or manager as being practicable, but it is very simple and to a certain extent it would diminish the difficulties and the cost of ventilation. As regards pollution by horses, it is not convenient always to have stables in the upcast shaft, but for the sake of the air they should be; for the sake of the horses the stables are better in the downcast, as where the stables are in the upcast pit experience proves that they do not live so long as in the downcast. Wherever the stables are, means should be taken to purify them; impermeable floors which can be washed out with water, lime-washed walls, and careful attention to daily cleaning out of litter, would all help the problem of ventilation.

Natural means should assist artificial; thus, if the mouth of the upcast shaft were bell-shaped, and by a weather-cock arrangement made so as not to face the wind, its aspirating action would assist the fan instead of rather opposing it, as it does with the present system; and in the case of the downcast a sail or brattice might be so arranged as to promote the down current. Further,

in the case of the downcast, all sources of vitiation should be removed from near its mouth, such as tar, oil, paraffin, etc., and there should be no chance of currents passing from the furnace holes down the shaft.

The Work of the Miner and its Effects.—Twenty years ago air was very bad in mines; ventilation was almost unknown, and the hours were very long. Nowadays the air is generally good; ventilation is efficiently carried on, and hours of work are short. The miner works hard whilst at his work, but he has short hours and many holidays. In the tables of statistics I have shown that phthisis, contrary to general opinion, is not a common disease amongst miners; and my own everyday experience for ten years in a large mining population supports those tables. In fact, I know of no disease peculiar to miners, or any disease in excess existing among miners. I have also consulted many other medical men practicing amongst colliers, and their opinion coincides with my own. In conclusion, I have to state, as my belief, that the conditions connected with miners' occupation are as favorable to health as those in the occupation of any other workmen, and this opinion is borne out by the vital statistics quoted.—*Brit. Med. Journ.*, Aug. 4, 1888.

LIKE AN ALARM OF FIRE.—The head of the Health Department of New York City has some very clear notions in regard to the great need for alertness in the management of infectious diseases. He has had occasion lately to write officially as to the imminence of yellow fever. From his letter we quote a paragraph which shows its author's confidence that this department is thoroughly equipped and disciplined. After remarking that yellow fever is not to be dreaded this year at our northern cities, he says, "If the fever should occur, however, it would be in isolated cases, with which we are prepared to deal so promptly and effectually that it will have no chance to spread. The machinery of the contagious diseases division of this department is in such condition that it can be set in motion at a moment's notice, and I am confident that the response of this department to a notice of known or suspected disease of a dangerous character would be like that of the fire department to an alarm. With special reference to yellow fever, we have a medical inspector constantly on duty at our headquarters. Within five minutes after receiving a report he would be on his way to inspect it, within thirty minutes we should have his report, and immediately an ambulance and the disinfectant's wagon would be despatched to the place. In an hour we should have the patient on his way to the hospital at North Brother Island."

When we reflect how much panic and harm often arise from a lack of preparation for such visitations, it is very gratifying and reassuring to read that a health official compares the readiness and discipline of his department with those of the model fire departments of our large cities, where everything is in motion at the touch of a bell.—*Medical News*, Sept. 1, 1888.

MEDICAL SOCIETIES IN KANSAS.—The *Kansas City Medical Record* in a recent editorial under the above caption says: A formidably harmonious county medical society, well attended and doing good work, will demoralize any incompetent opposition. The Kansas profession, we are pleased to note, are beginning to understand the situation, and societies are being formed in many parts of the State; good work is already inaugurated in these new societies, and with a united effort the State will be handsomely redeemed.

THE TRI-STATE MEDICAL ASSOCIATION of Mississippi, Arkansas, and Tennessee will meet in Memphis, November 13—the second Tuesday in the month.

CHOLERA has very nearly ceased in Cashmere, India, but it prevails still in many parts of the country, though not to any great extent.

Official List of Changes in the Stations and Duties of Officers Serving in the Medical Department U. S. Army, from September 22, 1888, to September 28, 1888.

By direction of the President Major George M. Sternberg, Surgeon U. S. Army, will proceed to Decatur, Ala., and to such other points in the infected districts of the Southern States as he may deem necessary, to continue his scientific investigations of yellow fever. Par. 8, S. O. 224, A. G. O., Washington, September 26, 1888.

Under authority from Hdqrs. of the Army, A. G. O., dated September 22, 1888, Major Charles B. Throekmorton, and batteries "K and M," Second Artillery, comprising the garrison of Jackson Bks., New Orleans, La., will precede at once, by sea, to New York Harbor, and upon arrival there will take post at Ft. Wadsworth, New York Harbor. A small guard of enlisted men will be left at Jackson Bks. Major John W. Williams, Surgeon, will accompany the troops to New York Harbor; Major Harvey E. Brown, Surgeon, will remain at Jackson Bks. Par. 12, S. O. 202, Hdqrs. Div. of the Atlantic, Governor's Island, New York City, September 26, 1888.

Major Robert H. White, Surgeon U. S. Army, is granted leave of absence for one month, with permission to apply for an extension of one month. Par. 7, S. O. 199, Hdqrs. Div. of the Atlantic, Governor's Island, New York City, September 22, 1888.

By direction of the acting Secretary of War, leave of absence for six months on surgeon's certificate of disability, with permission to leave the Div. of the Missouri, is granted to Capt. Ezra Woodruff, Asst. Surgeon. Par. 5, S. O. 223, A. G. O., Sept. 25, 1888.

By direction of the acting Secretary of War, Capt. Washington Matthews, Asst. Surgeon, is detailed as a member of the Army Medical Examining Board appointed to meet in New York City October 1, 1888, by S. O. 203, September 1, 1888, from this office, vice Major George M. Sternberg, Surgeon, hereby relieved from his detail as a member of the Board. Par. 3, S. O. 224, A. G. O., Washington, September 26, 1888.

Upon the recommendation of Capt. Daniel Weisel, Asst. Surgeon, senior medical officer camp of instruction of the Fifth Cavalry, Capt. J. Van R. Hoff, Asst. Surgeon, is assigned in charge of active operations of the hospital corps in that camp. Par. 2, S. O. 121, Hdqrs. Dept. of the Missouri, Ft. Leavenworth, Kan., September 22, 1888.

By direction of the acting Secretary of War, leave of absence, to include May 3, 1889, is granted Capt. George F. Wilson, Asst. Surgeon. Par. 14, S. O. 223, A. G. O., September 25, 1888.

The resignation of Capt. George F. Wilson, Asst. Surgeon, has been accepted by the President, to take effect May 31, 1889. Par. 15, S. O. 223, A. G. O., September 25, 1888.

Official List of Changes in the Medical Corps of the U. S. Navy for the Week Ending September 29, 1888.

Medical Inspector Adrian Hudson, ordered for examination preliminary to promotion to Medical Director.

Medical Inspector Newton L. Bates, ordered for examination preliminary to promotion to Medical Director.

Surgeon George H. Cooke, ordered for examination preliminary to promotion as Medical Inspector.

Medical Inspector Michael Bradley, ordered as member of Naval Examining Board.

Medical Inspector Henry M. Wells, relieved from duty as member of Naval Examining Board.

Surgeon Manly H. Simons, ordered to Widow's Island Naval Hospital.

P. A. Surgeon A. C. Heffenger, detached from naval hospital, Widow's Island, and wait orders.

SOME OBSERVATIONS CONCERNING THE EXTRACTION OF CATARACT WITH- OUT AN IRIDECTOMY, AND THE USE OF THE BANDAGE IN THE AFTER-TREATMENT.

Read in the Section on Ophthalmology at the Thirty-ninth Annual Meeting of the American Medical Association, May 9, 1888.

BY GEO. E. FROTHINGHAM, M.D.,

PROFESSOR OF OPHTHALMOLOGY IN THE UNIVERSITY OF MICHIGAN.

The question as to which is the best method of extracting senile cataract has lately been considerably discussed, and a return to the old flap operation, in all its essential features, has been advocated and carried into practice by several ophthalmic surgeons. Professor Schweigger has even abandoned the use of the narrow knife, and has substituted one very nearly of the same form as the one first used by Joseph Barth, the founder of the Vienna School of Ophthalmology, and adopted by Beer and commonly known as Beer's knife. In this respect Schweigger has returned to the practice of the great founder of modern ophthalmology, instituted over a hundred years ago. By this movement the cycle has been completed and we find ourselves at the point of departure. Movement does not always mean advance, however, and I believe that not only this return to the wide knife, but also the attempt to extract any cataract, hard or pasty, without an iridectomy, is a backward movement that a proper consideration of past experience should deter us from making.

To me the matter has been one of considerable interest, for, so far as I know, I was the first to devise the upward extraction without an iridectomy and using a narrow knife, as has lately been advocated by several operators. I published an account of this operation fourteen years ago, and claimed for it advantages that a more extensive experience proved to be unfounded. I soon abandoned it, I confess, not a little chagrined at having claimed such advantages for it, without a more prolonged trial and analysis of results.

When I first began to operate for cataract, about twenty years ago, von Graefe's extraction, devised but a few years before, had been almost universally

adopted both in Europe and this country. I knew of but one operator of note who still adhered to the flap extraction. I began to operate by making the flap extraction, but I soon abandoned the use of the wide knife, making the flap with a Graefe's knife and performing an iridectomy only when the iris offered unusual obstruction, or was injured in some way. I was induced to adopt this older method by a consideration of the danger that seemed to me inherent to the extreme peripheral incision advocated by von Graefe, and practiced by him and his followers everywhere at that time. This incision approached so near to the ciliary body that it seemed to me a dangerous position to inflict a wound; and, indeed, a few cases of cyclitis, ultimately involving the other eye, and seemingly due to the peripheral position of the incision, had already been reported. Besides this, the excision of the iris seemed like an unnecessary mutilation, and served to add to the traumatism from which the eye must suffer in the extraction. It seemed to me unwarrantable to incur these dangers, unless the operation could be shown to possess elements of safety that more than made up for these obvious disadvantages. Statistics had not then accumulated, as they have since, to substantiate the claims of Graefe's operation. But notwithstanding this, it was rapidly adopted through the magic influence of his justly celebrated name.

Probably the ease with which his incision is made, and the facility with which the lens can be extracted by his method, were not the least of the inducements that led to its rapid substitution for the more difficult flap extraction. It must be borne in mind that in the old flap extraction the incision was made with a wide triangular knife, known as Beer's knife. It required the greatest care and skill to complete this incision without allowing an escape of the aqueous fluid, and entanglement of the knife in the iris and various other complications that I need not mention now. Indeed, so much practice and skill was necessary to complete the incision in a suitable manner that surgeons generally hesitated to perform it, and quite generally operated for cataract by couching or displacement, long after that operation had been condemned by specialists as decided malpractice. One has only to read the statements found

at this period in any standard work on surgery, to see how formidable the operation seemed to them.¹ I remember now the many hours I spent in executing it upon the cadaver, and upon animals, before I attempted to make it upon a patient.

The flap when properly made, however, by reason of its large size, and lying in the cornea, just anterior to the sclero-corneal junction, allowed of a rotation of the lens upon its axis and passage through the pupil into the anterior chamber, from which it could generally be extracted without mutilating the iris. When a cure was effected, without accidental complication, there existed a central, movable pupil, and to the ordinary observer the eye seemed perfectly natural. Even on close inspection it revealed the absence of the lens only by the deep anterior chamber and tremulous condition of the iris. Indeed, its successful results were models of perfection. It was the ideal operation. Why was it abandoned? Besides the large number of cases lost by suppuration of the cornea, prolapse of the iris, and occlusion of the pupil, there were several reasons which were more or less important, that I shall not mention in detail here. The result from all these causes was that, even with the greatest operative skill that could be acquired, and the closest attention to after-treatment that could be bestowed, failure occurred so often that thoughtful operators sought for some method by which the dangers and failures might be lessened. The perfect results by this method were all that could be hoped for, and if "perfect results for the few" had been von Graefe's motto, he would never have proposed as a substitute the operation that bears his name. But, regarding "sufficient sight for the greatest number" as the prime object to be sought, he made the change, and soon reduced the number of failures to about one-third what they had formerly been, and complete successes he raised from 80 per cent. to 90 per cent.

Influenced by the considerations I mentioned at the beginning, I adhered to the flap operation until statistics, sufficiently extensive, should demonstrate the superiority of Graefe's extraction. Before this seemed to me established, Liebreich published his method of downward extraction, which he claimed to be as easy of execution as couching, as safe as Graefe's method, and as perfect in result as the flap extraction.

His operation was performed downward, the incision being made with a narrow Graefe's knife, the puncture and counter-puncture being about 1 millimetre external to the clear margin of the cornea, and a little below the horizontal meridian. From these points it was carried downward in a curved direction and terminated at a point about 2 millimetres above the lower margin of the cornea. Influenced by the claims thus made by so

distinguished an author, I tried it in several cases soon after his publication appeared. I was greatly disappointed, however, by finding, at the start, that the operation, contrary to his claim, was difficult in execution, for, by reason of the anterior position of the apex of the flap, I found it even more difficult to evacuate the lens without resorting to traction than in the flap operation, in which the incision was made more peripheral, and allowed of more ready escape of the lens under the influence of gentle pressure. Besides, Liebreich's method had the fault of downward extractions generally, and in case iridectomy became necessary the coloboma would be uncovered by the lid.²

From a consideration of this and other operations I devised an upward extraction somewhat similar to Liebreich's, but having the apex nearer to the sclero-corneal junction, only one millimetre or less inside of it, the puncture and counter-puncture being at about the same distance behind the margin of the clear portion of the cornea as in his operation. After making this operation a few times, I published a description of it in the Transactions of the Michigan State Medical Society for 1874, (page 237 *et. seq.*), and claimed for it superiority over other methods then practiced. From that report I quote the following: "The operation as I have performed it is made thus: the patient, having been chloroformed, a stop speculum is introduced and the eye fixed as in modified linear extractions. With a Graefe's knife the puncture is then made in the sclera, about a half a line from the margin of the cornea, and about a line, or a line and a quarter, below a tangent to the upper edge of the cornea; the counter-puncture is made in a corresponding position on the opposite side, and a flap is then carved out so that its upper edge shall be about half a line within the corneal margin. The capsule is then lacerated, and the other steps of the operation are the same as in flap extraction.

"The advantages of this method are:

"First, ease of execution:

"Second, as great safety from corneal suppuration as in the modified linear extraction.

"Third, as perfect results as by the flap extraction.

"Fourth, in case any accident requires an iridectomy, the coloboma will be covered by the upper lid, and thus the least inconvenience result."³

But I soon found it necessary to modify this operation very materially. I carried the apex of the incision farther backward, close, to the sclero-corneal junction, or even a little within, but still farther forward than Graefe originally recommended. I then made an iridectomy in all cases.

¹ See Gross' System of Surgery, fifth edition, vol. II, p. 320; also W. Lawrence, Treatise on Diseases of the Eye, p. 430, edition of 1833.

² He suggested that it could be made upward, but it does not appear that he ever attempted it.

³ Transactions of Mich. State Med. Soc. 1874, p. 240.

I was driven to these changes by the accidents and difficulties inherent to any extraction in which the incision is not as peripheral as consistent with safety to the ciliary body, and these will require an iridectomy for the easy and safe evacuation of the lens, and greatest freedom from complications during the after-treatment. Unless the incision is, at the apex, well forward, and the flap large, there will be very great difficulty in rotating the lens forward so that it will pass through the pupil into the anterior chamber before it engages in the wound. If it does not do so, the iris is pressed before it as it engages in the opening, and, overlapping it, holds it as a hood and prevents its evacuation without dangerous pressure, and then only by stretching and bruising the iris in a manner that would greatly endanger inflammatory reaction. Any attempt to draw the iris backward over the edge of the lens, and replace it within the globe behind it, would hardly diminish the injury to the iris itself, and would be very liable to lead to rupture of the zonula of Zinn and escape of vitreous. Indeed, it has been said that Graefe was led to perform iridectomy, not merely to facilitate the escape of the lens, but because he had noticed that the most severe and destructive forms of iritis that occurred after extraction by the old method, had their starting point from this bruised and stretched portion of the iris. Infection would certainly be more likely to follow the replacement of the iris after such an exposure to conjunctival secretions, and this would be best avoided by excision.

An analysis of the next sixty cases operated upon by me, by this method, after publishing the description and making the claims above quoted, showed that iridectomy had to be performed in eight cases to avoid excessive bruising and stretching of the iris, or such prolonged and excessive pressure to evacuate the lens as greatly to endanger prolapse of vitreous humor. Even then prolapse of vitreous occurred seven times (equal to $11\frac{2}{3}$ per cent.).⁴ There were three cases of suppurative iritis resulting in reopening of the wound, suppuration of the cornea and loss of the eye, and one case of suppuration of the cornea beginning in the wound, and also resulting in loss of the eye. Prolapse of the iris occurred eight times complicating the recovery, though none led to immediate loss of the eye. There were fifty-one good results (85 per cent.), five partial successes ($8\frac{1}{3}$ per cent.), and four total failures ($6\frac{2}{3}$ per cent.) Cases in which the vision was $\frac{1}{16}$ or above, were counted as good results.

To be brief, I found the operation without iridectomy, tedious, and more likely to be at-

tended with prolapse of the vitreous than when iridectomy was made, and this I believe will be the experience of other operators. In twenty-four cases of uncomplicated hard cataract, operated upon by this method and reported by Dr. Chas. S. Bull, prolapse of the vitreous occurred three times, and the lens had to be removed by a traction instrument.⁵ This indicates something wrong with the operation itself, for prolapse of the vitreous need occur but seldom in extraction with iridectomy. It does not occur, on an average, in more than 3 per cent. of my cases now. Again, lens matter was more often left in the eye, not only behind the iris, but scraped off by the protruding sharp upper lip of the wound, it became packed into Fontana's space, from which position it was very difficult, and sometimes impracticable to dislodge it. Iritis and occlusion of the pupil occurred with greater frequency than it has since in my practice, and the dense plug, formed by the remains of lens matter and iritic effusion, constituted some of the most difficult cases to relieve by secondary operation. Schweigger confesses that more than 50 per cent. of all his cases heal with posterior synechia. (*Archives of Ophthalmol.*, December, 1887, p. 453.) One frequent source of danger and annoyance, namely prolapse of the iris, seemed to me almost certainly avoidable by the performance of an iridectomy. This occurred in one of my cases five days, and, in another, four days after the operation, and to patients who had kept reasonably quiet.

In the cases already reported, I notice a repetition of my experience. In forty-eight cases collected in Boston, by Dr. Derby, in which this operation has recently been made by skilled operators, prolapse occurred in twelve cases, or one in four. In one of these it occurred without cause in a docile patient four days after operation.⁶ Schweigger in his report of his first ten cases operated upon by this method, cites one case of prolapse of the iris in the whole length of the wound. This equals 10 per cent. He expresses the hope that this per cent. may be lessened in future cases. (See *Archives of Ophthalmology*, December, 1887, p. 451 and 452.)

This danger I believe cannot be wholly, or even largely, guarded against by the use of myotics. A year ago I was performing an extraction under cocaine upon a female patient who seemed to have the usual fortitude until the operation had been begun and the incision made. She then became unmanageable, and so strained the ocular muscles that vitreous began to escape quite freely before I had begun the iridectomy. I immediately introduced a sharp hook, and with its back pushed the iris backward over the equator of the lens and burying its sharp point in the nucleus below the

⁴ This experience is not exceptional as may be inferred from the report of two operations by Schweigger, in both of which an iridectomy became necessary, and in one vitreous escaped, and in the other the soft lens matter had to be removed with the scoop. See *Archives of Ophthalmology*, December, 1887, pp. 452 and 453.

⁵ *Transactions American Ophthal. Soc.*, 1887. Cases 11, 12, 13, of table following page 418.

⁶ *Boston Medical and Surgical Journ.*, Feb. 23, 1888, p. 180.

centre, drew the lens, together with its capsule, from the eye. The iris did not then prolapse, but resumed its normal position, the pupil contracting as usual when the aqueous chamber has been emptied. Performing the toilet of the wound, I instilled a solution of sulphate of eserine (2 grains to the ounce), and applied the bandage. Eserine was instilled regularly and all seemed to be going on well when, on the fourth day, without undue exertion on the part of the patient, a sudden pain occurred in the eye, and on examination the wound was found to have reopened and the iris was prolapsing. This case recovered only after a prolonged convalescence, and several operations, and then with a pupil drawn upward toward the wound. The effect of mydriatics, I believe, is too transient to maintain contraction of the pupil without too frequent instillations, and injurious meddling with a eye after operation for cataract. Besides, it is not rational to expect them to contract the pupil powerfully enough to resist the outward gush of aqueous humor which tends to carry the iris through the wound when it is suddenly broken open by the intraocular pressure.

I need not dwell upon the gravity of this annoying and dangerous accident. It is in most cases only remedied by resorting to a severe operation before the eye has recovered from the traumatism of the extraction, and recovery is generally tardy and often incomplete. Prolonged irritation may ensue, and cyclitis follow, with ultimate destruction not only of the eye operated upon, but the other through sympathy. My experience with this troublesome complication led me to bring the apex of my incision just at the sclero-corneal junction, and thus avoid so large a flap, and also to make an iridectomy in all cases, as a preliminary step to evacuation of the lens. At first I sought to remove as little of the iris as possible, thinking this would allow of easy evacuation of the lens during operation and also of an unobstructed escape of aqueous in case of a sudden reopening of the wound, and thus avoid the extensive prolapse of the iris that would result when it is left entire. In such a case the iris forms a sac, holding the aqueous and acting as a dilator to separate the lips of the wound, often to the utmost extent. I found, however, that when the iridectomy was small the iris still offered some obstruction to the escape of the lens, necessitating a larger flap than would otherwise be needed, and also that an occasional prolapse of the iris at the angles of the wound would occur during the after-treatment. Though these were not so dangerous as the extensive prolapses that often occurred when no iridectomy was made, they still constituted a not very infrequent and quite troublesome complication. These accidents led me to enlarge my iridectomy and I now always aim to remove a large section of the iris. While but a small portion of the pupillary border is cut away,

I seek to remove a large portion of the periphery, in fact, nearly all of that portion that lies behind the incision. The iridectomy thus made is as large as we would attempt for the relief of glaucoma.

I am aware that many operators severely criticise such an iridectomy, and I think of but one distinguished ophthalmologist who professes to practice it.⁷

I have found this large iridectomy not only a safeguard against prolapse, but also against those glaucomatous attacks so painful and dangerous at times during a late attack of iritis following extraction without an iridectomy, or when only a small iridectomy has been made. A large iridectomy also allows of a safer extraction, and a more complete evacuation of soft lens matter, and that, too, with a smaller flap than would otherwise be required. The danger of suppuration of the cornea is thus greatly lessened. The coloboma, in an upward extraction, is so largely covered by the upper lid as to give rise to very little visual disturbance.

In the after-treatment of cataract extractions I deem the application of a bandage covering both eyes, a very important measure. Properly applied, it helps to ensure the healing of the wound, and lessens the dangers of internal inflammations also.

The bandage should be applied in such a way as to exercise gentle pressure upon the orbital portion of the orbicularis muscle. By means of absorbing cotton, properly packed into the depressions about the globe, it serves also to exercise some pressure about it in such a way as to maintain the convexity of the cornea, and more complete coaptation of the flap. This, by some, may be thought a fanciful measure, but it is rational practice, in my opinion. Slight pressure, not uncomfortable in degree, often serves to prevent that troublesome attempt to wink that is annoying to some patients, and which may prove injurious just after an operation. The unoperated eye should be closed and covered with a compress and bandage, as well as the eye operated upon. This, I believe, is of great importance, for, if the unoperated eye is left open, the necessity to wink will exist, and every time the lids of this eye close, there will be a similar, sudden, spasmodic contraction of the orbicularis of the operated eye. This will compress the globe, and must cause a slight motion of the lips of the incision, unfavorable to speedy union. In the case of a fractured bone, such a motion would be regarded as very dangerous to the proper healing process, and bony union might be wholly prevented. It can have only an evil influence upon the healing of the wound after a cataract extraction.

⁷ E. Landolt. See discussion at Ninth International Med. Congress in the American Journal of Ophthalmology, Sept. 1887, p. 261.

If any one will place two or three fingers lightly upon the closed lids of one eye, while the other is left open and winking, they can readily demonstrate the strong contractions of the lid of the closed eye, which take place every time the winking occurs in the eye that is left open. These contractions are strong, and must give rise to a sudden and decided compression of the globe, that cannot occur without producing some motion of the lips of the wound.

Again, if the unoperated eye be open and used, every motion of the ball will be attended with a corresponding motion of the operated eye. This will be likely to cause gaping of the wound and occasional evacuation of aqueous, and perhaps prolapse of the iris also. Even the exposure of the unaffected eye to light acts as an irritant to the other. This is a matter of physiology well known. It would tend to produce inflammatory reaction when it might not otherwise result. If inflammation has already commenced, it would serve to intensify it. In every case of injury, followed by inflammatory reaction, we find the patient complaining that use of his uninjured eye aggravates the pain, if present, in the one injured. Often such an exposure of the well eye is the only exciting cause of pain in the injured one, there being no pain in it when the other eye is not used or exposed to light. These examples are sufficiently numerous to enable us to establish the principle that *when one eye has been subject to severe traumatism, the other should be shielded from light, and use of it, as much as possible, avoided.* More than this, the bandage and thick cushion of cotton serve to protect the eye from accidental blows that may otherwise do harm, and is much easier to remove than plasters generally are.

The patient should be confined in bed. It is here that he can be kept most quiet and his circulation in the best condition to avoid inflammatory affections of the interior of the globe, that are so frequently a cause of failure after an extraction. If an iritis exists we would certainly require confinement to bed. If we could control our patients suffering from any form of iritis, we would confine them all to bed. Our failure to cure the disease, and the prolonged course which many cases pursue, may be justly attributed to the fact that the patient goes about, and is thus exposed to influences that tend to cause relapses and aggravate the disease in all its stages. Why should we court this danger, always liable after cataract extraction, by allowing a patient to be dressed and to go about almost at pleasure, as some propose to do? It has frequently occurred in my practice, that everything has gone on well until the beginning of the second week, when some slight exposure on the part of the patient who is allowed to be up and dressed, has provoked an obstinate iritis. If I could have my way I would keep all imprudent patients in bed, and

under the care of a discreet nurse, for full two weeks after an extraction.

As a result of experience in making over seven hundred extractions, over two hundred of them being flap operations, I have come to the following conclusions:

First. That a narrow, sharp pointed Graefé's knife is the most convenient instrument with which to make the incision for the extraction of hard, half hard, or pasty cataracts, whether an iridectomy is to be made or not. It is the only knife with which a suitable flap can be made, one with edges in such a form as to remain in proper coaptation under the pressure of the lids.

Second. The incision should not be farther forward than the sclero-corneal junction at the apex, and at the lower angles should be about one and a half millimetres behind it.

Third. A large iridectomy should be made, so as to remove obstruction to the escape of the lens, and avoid the danger of prolapse in the course of recovery.

Fourth. The flap should be as small as possible and yet allow of an evacuation of the lens without undue pressure.

Fifth. Extraction without iridectomy requires a larger flap than would otherwise be necessary, and thus adds to the risk of suppuration of the cornea. It does not allow of so complete evacuation of lens matter. The retained lens matter, together with bruising and stretching of the iris; adds to the danger from iritis following the operation.

Sixth. The dangers of extraction may be greatly lessened by performing a preliminary iridectomy two or three months previous to the removal of the lens.

SECTION OR EXSECTION OF THE RECTUS

IN THE TREATMENT OF PARALYTIC STRABISMUS, AND THAT DUE TO EXTREME OVER-CORRECTION WITH LOSS OF MOTION.

Read in the Section on Ophthalmology at the Thirty-ninth Annual Meeting of the American Medical Association, at Cincinnati, May 7, 1888.

BY ARTHUR E. PRINCE, M.D.,

OF JACKSONVILLE, ILL.
OPHTHALMIC AND AURAL SURGEON TO THE ILLINOIS STATE INSTITUTIONS FOR THE DEAF AND DUMB AND BLIND.

The purpose of this paper is the presentation of a series of cases of *irrecoverable* loss of power of either rectus, causing extreme paralytic deviation, the restoration of the equilibrium having been accomplished through *section* or *exsection* of the contracted muscle. Such cases are found in one of the four following classes:

1. Permanent atrophy or paralysis.
2. Irrecoverable loss of either rectus through accidental section of the muscle back of its capsular perforation.

3. Extreme over-correction of long standing, following tenotomy with excessive laceration of the capsule, permitting the retraction of the tendon back of the equatorial meridian, whence, owing to atrophy or adhesions it cannot be successfully advanced.

4. Irrecoverable traumatic dislocation of the rectus.

Cases belonging to the paralytic class are not very infrequent. The class of accidental section of the muscle in place of the tendon (formerly very large before the relations of the capsule were understood) is assuming diminished proportion, and new cases are seldom produced except by the most inexperienced charlatan.

The third class is becoming smaller in proportion to the attention paid to the preliminary correction of ametropia, and the frequency with which advancement is employed in the correction of high degrees of squint.

In the fourth class my knowledge is limited to the observation of case 7.

The clinical aspect of these conditions needs no particular consideration. The unpleasant appearance of an extreme deviation, especially when outward or upward and accompanied by restricted motion, is too familiar to be mistaken. The exceptional reference, if any, to be found in the literature of treatment, and the acknowledged incapability of tenotomies and advancements to correct these deformities, justifies the brief outline of the following cases, which have led to the adoption of the present mode of practice.

Case 1.—One of a series of unsatisfactory results, following attempts to correct a paralytic condition, by advancement.

Mrs. D., aged 45. In childhood both interni had been tenotomized in an unknown manner, resulting in a moderate over-correction, which later in life became a divergence of both eyes, measuring together 70° . The interni were so inefficient that the axis of neither eye could be brought parallel to the meridian plane. Lateral motion was restricted to 30° in the right, and 25° in the left eye. The operation performed was a tenotomy of the externi with advancement of the retracted interni recti. The interni were found remotely attached to the posterior hemisphere of the ball, but the advancement was accomplished in a satisfactory manner, and the result was a temporary success. Soon after her discharge a slight divergence (10°) was observed, but in contrast with the gravity of the former condition was not regarded as a bad failure. For three months the divergence increased until it would have been difficult without actual measurement to determine any material improvement.

This failure is introduced as a type of the results which will attend the attempts to restore the equilibrium through advancing a muscle which has remained for many years retracted in the orbit,

becoming atrophic through inactivity. The superior strength of the opposing muscle, though tenotomized, will assert its supremacy and the correction will not be permanent.

Case 2.—*Section of both recti, posterior to their capsular perforation.*¹—Barney Burnes, Sydney, Ill., aged 43. From infancy to the age of 20, he was the subject of a marked internal squint. At that time his father entertained a guest over night who made it his business to travel the country and straighten cross-eyes. It was considered a rare fortune thus accidentally to have presented an opportunity which might never occur again, for they were very poor, and he was willing to straighten both eyes for his lodging and \$2.50. A week later, when Dr. Strabotomist was pursuing his calling many miles away, it was considered safe to expose the eyes to the light, when the following condition was revealed.

Both eyes were deviated extremely outward, measuring with Snellen and Landolt's method,² 50° in the right eye, of which a portion of the iris was concealed under the external canthus and the lateral motion limited to 10° . With H.=I. 5 D. corrected, V.= $\frac{2}{30}$. In the case of the left eye external deviation was 40° , lateral motion 15° , H.=I. 5 D., V.= $\frac{2}{40}$. Direct vision was very imperfect, but by turning the head to bring objects in the visual axis of either eye he could see tolerably well. As he was very anxious to have an effort made for the correction of his deformity and bearing in mind my experience with advancement in this class of cases, it was explained to him that his muscles had been divided too far back, to correct which, as had an operation would be attempted on the external muscles, as his \$2.50 operation had been on the internal muscles, and that it was hoped by the aid of a stitch to be able to effect a parallelism, so that he would look well and have direct vision, but he must not expect to have lateral motion, for with the lateral rectal attachments of both eyes destroyed, the must be satisfied if they were simply straight. With this understanding the operation was undertaken. A lateral incision was made above each external rectus and the hook introduced far back, exposing the muscle, which was divided outside the capsule. An internal advancement suture, to avoid subsequent deviation, was placed in each eye. The after treatment consisted of a moist compress of carbolic acid, $\frac{1}{2}$ per cent. No pain followed the operation, which was done under ether. On the fourth day there was an inward deviation of 5° , which was not noticeable. No deviation has occurred in the interval of seven years which have elapsed.

¹ The liberty is taken of reproducing this and the following case from the Pulley Method of Advancing the Rectus. N. Y. Medical Record, Aug. 8, 1885.

² Bestimmung des Schielens, Snellen u. Landolt. Handbuch der Augenheilkunde, Graefe und Saemisch, vol. III., p. 235.

³ Manual of Examination of the Eyes, Landolt, p. 49, ed. 1879.

⁴ Traite d'Ophthalmologie, Landolt, and Wecker, vol. 1, p. 915.

The most gratifying and at the same time surprising fact, especially worthy of note, was the unpredicted amount of *lateral motion*, which in the right eye amounted to 40° , and in the left to 45° . To account for this unexpected success the theoretic explanation was advanced that both external and internal recti formed a union with the posterior hemisphere of the capsule, for it is scarcely probable that so great an amplitude of motion could be accomplished by the recti muscles acting alone on the orbital cellular tissue. Another consideration (concerning which it must be confessed some apprehension was entertained) was the danger of *exophthalmos*, consequent on destroying the ocular attachments of the two opposite recti muscles. The entire absence of this effect is likewise regarded worthy of note.

My enthusiasm led me to secure photographs of his condition before the operation, and also before his departure ten days subsequently.

Being in the city, the courtesy of Dr. Webster was extended in an invitation to demonstrate the *puller* method of advancement on the following day at the Manhattan Eye and Ear Infirmary. Judging from the amount of motion obtained in the case related above, it was thought that a simple section of the muscle back of the capsule would be insufficient; that an attachment to the posterior hemisphere would probably occur and reproduce a partial internal deviation. It was therefore determined to exsect the muscle as far back as possible, the intention being to destroy the efficiency of the internal rectus. Under the influence of cocaine, the globe was rotated with fixation forceps as far to the temporal side as the contracted and hypertrophied muscle would permit, in order to allow of the introduction of the hook. Parallel lateral incisions were made, liberating the muscle, which was drawn out by the continued traction of the hook and divided at the

Case 3.—*Complete paralysis of the 6th nerve, treated by exsection of the rectus internus.*—Mr. T. A. D., Oneida, N. Y., aged about 30 years, presented himself at the College of Physicians and Surgeons, New York, with a condition of complete paralysis of the external rectus of the left eye, following a railroad accident twelve years since. In the collision his head was jammed between two cars. The recovery from the injury was rapid, leaving no other effects than an extreme internal deviation with partial concealment of the iris. Some years after an unsuccessful operation was performed. Tested at the College and also at the Manhattan Eye and Ear Infirmary: V.=counts fingers at 6 inches, internal deviation about 50° , absolutely no motion.

remotest accessible point. The anterior portion was then separated from the sclera. An external advancement suture was inserted to hold the eye in position, and it was kept moist with a saturated solution of boric acid. No especial reaction followed the operation. The stitches were removed on the fourth day. The eye was perfectly straight. No exophthalmos or unnatural appearance existed except the absence of lateral motion. After a week, V.= $\frac{3}{4}$; in a direct line had binocular fixation, but lateral motion of the head either way caused diplopia. He left the hospital satisfied, with still some little ecchymosis, rapidly absorbing.

Case 4.—*Exsection of the anterior portion of the externus for the correction of a paralytic divergence*

following faulty operation for internal strabismus 44 years ago.—Mrs. H., Carrollton, Ill., aged 53. At 9 years of age had an operation for the correction of convergent strabismus, resulting in an extreme over-correction of the left eye only. The angle of the deviation was 45° , and the lateral motion did not exceed 10° .

The staring effect of the divergence, combined with the loss of motion, was a constant source of embarrassment. She was especially anxious to have the deformity corrected, since in the capacity of wife of a Methodist minister she frequently changed her abode and made new acquaintances.

With an understanding that parallelism, with but partial restoration of motion was all that could be certainly secured, it was determined to advance the internus if possible; to exsect a portion of the externus if necessary.

Under cocaine an incision over the internus was made and forceps introduced to secure the retracted muscle, which was found but could not be satisfactorily advanced owing to the cicatrization and long-standing contraction of 44 years. A suture was introduced to be subsequently employed to overcome the divergence. The tendon of the externus, secured by fixation forceps, was then separated from the sclera and freed from its capsular attachments by four incisions parallel to its course. Thus permitted to assume its meridian plane, it was brought into and secured in this position by the suture previously placed in the contracted internus. Lastly the anterior confused end of the externus, thus far held by the forceps, was removed, allowing the muscle to retract into the orbit. The stitches were removed on the fourth day, when she went to her home, from which she has written expressions of satisfaction with the result. Motion is very good and I regret not being able to give it in degrees. No exophthalmos exists.

Case 5.—Exactly similar to the preceding.—Mrs. S., Springfield, Ill., aged 54 years. Operated for internal squint at 10 years of age. Slight divergence of the left eye at first, became more marked as she grew older, partly owing to the relinquishment of her accommodation ($D = +2.5$ D—). She gradually lost control of the lateral motion which was reduced to 5° , and finally consulted me concerning pain which was assumed to be due to the permanent contraction of the externus.

The foregoing considerations led to the adoption of the method of treatment employed in the previous case, with similar results, except that the lateral motion obtained was more limited, not exceeding 20° . The eye appears straight during direct vision, pain has disappeared and she has been enabled to do an indefinite amount of sewing without discomfort. No increased prominence of the eye can be observed.

Case 6.—Similar to the two previous.—M. K.,

Kansas. Mr. K. is a German Lutheran preacher. He states that extreme divergence of the right eye resulted soon after an operation for internal squint. This occurred in childhood while he was still in Germany.

One operation for the correction of his deformity had failed, but he was sufficiently intelligent to appreciate the method suggested, of first accomplishing what was possible by an advancement and then weakening the externus sufficiently to restore a balance of the opposing forces.

The mechanical procedure was a repetition of the foregoing, and the result satisfactory to the patient. The lateral excursion amounted to 35° . There was no apparent exophthalmos.

Case 7.—Dislocation of the inferior rectus, and divergent strabismus 25° , following injury; treated by exsection of the superior, tenotomy of the external, and advancement of the internal recti.—Mr. J. P., Camden, Ill., aged 30 years. Fourteen years ago, while walking under a tree, he was struck in the right eye by a broken branch, causing him to fall to the ground. For three hours he suffered pain and nausea. The eye was dressed by Dr. Mead, of Huntsville, who removed some pieces of bark, after which the swelling was too great to permit inspection for eight days. At that time the eye was found deviated upward, carrying the upper lid with it. There was no power of downward rotation. The eye deviated also outward, but had lateral motion good. He reports the condition to have suffered no change since the injury. The external deviation is found 25° , and the upward deviation 30° , and paralytic. The maximum of lateral motion not noted.

The eye appears slightly exophthalmic. The upper lid would descend by a voluntary effort, but in the condition of rest it was elevated, making the vertical diameter of the palpebral fissure one-half greater than that of the fellow eye.

By an effort at closing the lid slight downward motion of the ball was effected. The permanent upward rotation of the eye subjected the inferior portion of the cornea and adjacent sclera to continued exposure, causing it to be always congested, and at times badly inflamed, preventing sleep. No epiphora existed.

Operation.—The correction of this rare deformity was planned as two operations. The first, to restore a balance of muscular efficiency in the vertical plane. The second, to correct the external deviation in the horizontal plane.

Under the influence of cocaine an incision was made over the location of the inferior rectus. By the grasp of the forceps muscular action was observed, but owing to the extensive long-standing cicatrization, no effective advancement could be made. An inferior advancement stitch was introduced and an attachment made to the sclera. The next step was to weaken the superior rectus sufficiently to permit the enfeebled inferior suc-

cessfully to oppose the force of its antagonist. Accordingly, its tendon was detached from the sclerotic and secured by the forceps. The effect not being sufficient, the muscle was liberated from its capsular attachment by incisions parallel to its course. It was thus rendered possible, by means of the inferior advancement suture, to secure a parallelism in the horizontal plain. The superior rectus was then shortened and allowed to retract back of the equatorial meridian of the eye, that it might not overbalance the strength of the dislocated inferior rectus. The immediate result was good. Some vertical motion was restored. The lids closed naturally, covering the ball.

Three days later the patient reports slight pain since the operation. Conjunctiva much congested. Vertical motion 30° . Amount of exophthalmos unchanged, but less conspicuous, owing to the closure of the lids over the sclera.

April 20, 1888, two months later. Returned for the correction of the external strabismus, which still remains 25° . At this time there was 5° of superior deviation. Vertical motion measured 30° .

The external deviation was corrected by a tenotomy of the externus with an advancement of the internus, one suture being inserted into the muscle, and the other into the episcleral tissue forming a pulley over which the advancement can be made with precision to any required degree, securing with a bow-knot, to permit of subsequent modification, as explained in a communication to the *Ophthalmic Review*, Sept., 1887.

The following cuts, which scarcely require explanatory text, may aid in the elucidation of the method of advancement attempted in each of the above cases.

Figure 1.

By the aid of the needle, figure 1, it was found possible to insert the advancement suture, though the muscle itself could not be brought into view.

CONCLUSIONS.

The conclusions suggested by the above cases are: 1st. In the case of complete paralysis of either rectus, the exsection of the opposing muscle will enable the eye to be retained in the straight position, without motion in that meridian.

2d. In case of retraction of either rectus muscle into the orbit, under conditions rendering its advancement impossible, an equalization of the deviating power is to be obtained through section of its antagonist, posterior to its capsular attachment, following which, excursions in that meridian will be restored to an extent varying between twenty and fifty degrees.

3d. In the above cases of paralysis, or retraction of either rectus, the operation of section or exsection of its antagonist has not been observed to develop or increase any preëxisting exophthalmos.

Figure 1.

ON THE CREMATION OF GARBAGE.

Read in the Section of State Medicine, at the Thirty-ninth Annual Meeting of the American Medical Association, Cincinnati, May, 1888.

BY J. BERRIEN LINDSLEY, M.D.,
OF NASHVILLE, TENN.

Very few persons outside of the limited circle whose official duties place them in constant contact with the offensive topic have any conception of the enormous amount and varied character of the filth generated by the daily life of a great city.

Hence they do not understand why it is that practical sanitarians are everlastingly harping upon *cleanliness* as the *sine qua non* of civic health; and earnestly calling for stringent legislation and large appropriations to enforce and carry out sanitary ordinances which shall maintain a pure soil within the city limits.

Practitioners of medicine understand that pure air, or impure air, has immensely to do with success or failure in the treatment of all diseases. Hospital and prison history for the past century, and infant mortality in cities and towns has made this a familiar fact. Few, however, understand that it is perfectly possible to render the atmosphere of even the largest cities pure enough for infants and invalids to grow and recover.

As showing the great quantity and variety of polluting material occurring without pause within the limits of a city, two or three examples may be given.

Baltimore, August, 1887, estimated by police census, had a population of 437,155. The amount of night-soil delivered at the dumps for the year ending December 31, 1887, was 51,107 loads, or 10,221,400 gallons. Probably more than half the inhabitants use water-closets, which carry off an equal amount. The dead animals, etc., removed during the same year, were :

Total number of dead animals	25,249
" " " fowls	9,074
" " " fish	23,574
" " cart-loads of dead fish, vegetable and other offal removed from various docks	1,067
" number pounds of decayed meat condemned	1,495
" number dozens of eggs condemned	607

Richmond, population 100,000. The report of contractor for removal of garbage, or kitchen refuse, year 1887, shows total number of loads carried off, 2,680 = 72,200 bushels.

Memphis, population 62,335. Number of loads of garbage removed in 1887 was 29,120.

These examples are selected at random. To keep the city clean is the principal work of municipal governments, and requires more expenditure of money than all other objects combined, excepting schools and police.

The city filth naturally falls into four main subdivisions—street sweepings, night-soil, dead animals, and garbage. The latter alone concerns us at present. The definition of garbage is refuse animal and vegetable matter from the kitchen. Every household is a workshop for garbage. In the country and small villages many a family is poisoned by the careless accumulation of the same near the well or sleeping apartment. In small towns it is mainly got rid of by feeding to swine and cows. In larger communities by carting off and polluting harbors or rivers.

Very recently, a great improvement has been introduced, to-wit, the destruction of garbage by fire. The object of this paper is briefly, but emphatically, to call attention to a great sanitary device which is not getting into public use near so rapidly as it ought.

In the Second Report of the State Board of Health, of Maine, 1887, the Secretary, Dr. A. G. Young, says : "Of the several methods which

have hitherto been in use (for removing garbage), it may be said that none of them are free from serious objections. If the garbage is carried any considerable distance into the country its transportation is attended with considerable cost. If buried, it still often remains a nuisance by contaminating the air or polluting the water in the neighborhood. If utilized in part as food for swine or cows, there is sometimes inflicted upon the community which sends it forth a retributive penalty in the shape of an unwholesome milk and meat supply.

"In the case of a sea-board town, if it is sent seaward, the garbage may depart from the place of its origin never to return, but in large part it is strewn along other coasts.

"The great desideratum has seemed to be some method which would not require a costly transportation of the garbage, or necessitate the defilement of our sea-shores, but which would radically and ultimately destroy it near the place where it is produced.

"Within the last few years a new method of disposing of garbage has been written and talked about, and to a considerable extent put into operation and practically tested. It is the method of destroying, or cremating, garbage by means of furnaces specially constructed for that purpose. Where these furnaces have been put into use, there is pretty uniform consensus of testimony as to their success. When rightly built they have done their work satisfactorily, and generally at considerably less expense than has hitherto been incurred in disposing of the garbage otherwise. But little or no cost is incurred for fuel to run the furnace, as the garbage is dried more or less before it is burned and is made to consume itself. The cost of labor in attending the furnace is not great, and generally there are no unpleasant odors given off in the process of burning.

"This method has not been much used in this country, but in Europe, and particularly in England, it has been extensively employed. Dr. O. A. Horr, a member of this Board, who has lately returned from Europe, made special inquiry in regard to garbage cremation in England, and all he could learn convinced him this system is a success in that country. The garbage furnaces in many of their towns have been in operation many years, and, in conversation with the Health Officer of the City of London, he learned that there are now forty-five of the English towns which make use of this method of garbage destruction.

"In this country, as far as I know, the experiment of destroying garbage by means of a furnace constructed especially for that purpose, was first tried on Governor's Island, New York Harbor. A description of this garbage-cremator was given in the *Sanitary Engineer*, of August 13, 1885, by Lieutenant Reilly, at that time Acting Assistant-

Quartermaster, U. S. A., at that post." This description is reproduced in the report above quoted.

In the twelfth volume of "Public Health," containing the reports and papers presented to the American Public Health Association, at the Toronto meeting, October, 1886, may be found a paper by Dr. George Baird, of Wheeling, giving an account not only of the destruction of garbage, but also of night-soil, by means of a furnace contrived by M. V. Smith, M. E., Bissell's Block, Pittsburgh, Penna. Dr. Baird is brief, and has "only tried to furnish proof of its capacity to solve a long-tried problem in the government of our cities and large towns."

The city authorities of Wheeling were stimulated to action by those of Bellaire, Ohio, on the opposite side of the river, but in close proximity. The dumping of night-soil and garbage from Wheeling into the Ohio river had become an intolerable nuisance to the inhabitants of Bellaire living just below. No alternative remained but to abate the nuisance. A similar alternative will soon be forced upon many of our riverside cities and towns. Law will decide that rivers do not belong to those who happen to dwell near the source, but equally to all below, and that the upper few have no right to deposit their filth in floating columns upon the lower many.

In the "Report on the Sanitary State of Montreal, for the year 1886, will be found an interesting narrative in this connection, giving instructive details as to cost, showing the extent of the work to be done and the complete success of the refuse crematories, and also of the night-soil crematories constructed by Mr. Wm. Mann. Dr. Louis Laberge, Health Officer of Montreal, read an elaborate paper on this topic at the meeting of the American Public Health Association, in Memphis, last November, which will be found in the thirteenth volume of "Public Health," now in press.

It thus appears that Wheeling and Montreal are the pioneer cities in arousing public attention to the cremation of garbage and night-soil. Other cities are taking hold of the experiment with much enthusiasm. The *Sanitary News*, of Nov. 19, 1887, states that at Des Moines, Iowa, a small Engle furnace is in experimental use, and is working very satisfactorily. At Pittsburgh a Rider furnace has just commenced its service. In Chicago a Mann furnace was being constructed. In the same valuable journal, March 17, 1888, may be found a full description of the Chicago garbage crematory, from which a duplicate of the plant could be built if desired. On April 14, it reports that the said crematory is doing good service in disposing of about fifty tons of material a day. The *Sanitary News*, of March 10, 1888, reports the success of the disposal of garbage by cremation at Milwaukee.

All who are concerned in this important subject will look forward with great interest to a paper on cremation to be read at the Milwaukee meeting of the American Public Health Association, November next, by Oscar C. DeWolf, M.D., the eminent Health Commissioner of Chicago.

We have seen how very recent is the resort to cremation in America for getting rid of garbage and other refuse; and it may with truth be claimed that Mr. J. M. Keating, the distinguished editor of Memphis, familiar with epidemics, first set this ball in motion. At the Indianapolis meeting of the American Public Health Association, October, 1882, he presented a paper on "The Cremation of Excreta and Household Refuse." He closes the paper thus: "There is no real safety save by cremation. Yankee ingenuity, once directed in this channel, will doubtless be equal to the emergency, and provide just the kind of cheap furnace or stove necessary for the purpose. By this means, and this alone, can the ultimate of sanitation be realized."

Already, in 1879, Mr. Keating had presented his views on this subject through the *New York Herald*, and with the endorsement of that influential paper. In the American Public Health Association, however, he had a deeply interested auditory of experts, and his views attracted much attention. He was induced by many of its active members to prepare an elaborate paper for its meeting at St. Louis, October, 1884, which was published under the title, "The Ultimate of Sanitation by Fire." This is probably the most complete and thorough monograph on the subject in the English language. It was widely circulated in the volumes of the American Public Health Association and through other channels.

Individually I subscribe to the principles and practical conclusions maintained and explained by Mr. Keating, and feel quite confident that in a few years Yankee inventive ingenuity will provide in great perfection the apparatus necessary for daily and cheap use. On this occasion I have confined myself to the cremation of garbage, because I am convinced that it will speedily come into use throughout America with like rapidity as has electric lighting, and will pave the way for a wider and more perfect application of sanitation by fire.

DR. JOHN MORRIS, of Baltimore, Md., thought the speaker's views would meet with general support. The interest in the topic was evidenced by the increasing number of garbage crematories. The health officer of Baltimore has recently visited Pittsburgh to inspect the operation of the garbage crematory in that city, with the intention of building a similar one in Baltimore.

DR. JONES, of Cincinnati, O., referred to the epidemic fever at Bellaire, O., which was due to the faulty method of garbage destruction. With

all health officers he agreed that an improvement in this would conduce greatly to the extermination of such epidemics; and only by burning the garbage was a possible source of disease eradicated.

DR. W. L. SCHENCK, of Kansas, agreed with the ideas expressed in the paper, and believed there was no other way as yet discovered to solve the problem of garbage destruction than by cremation. He was brought up on the Miami River, which was then a beautiful stream; now it was so polluted by garbage thrown into it, that the water could not be used for domestic purposes.

DR. LEE, of Pennsylvania, said, apropos of sanitation by fire, a good many who are present at this meeting attended the meeting of the American Public Health Association when the late Dr. Germer, of Erie, described the methods of sanitation by fire employed at the pest-house at Erie, Pa.—a can of kerosene and a match. There appeared to be no doubt that the future will demand sanitation by fire. Pittsburg had to meet the question, and devised a very satisfactory refuse crematory, in which he had seen wet tan bark consumed, and this was certainly satisfactory evidence of the efficiency of the crematory.

DR. MORRIS, of Baltimore: The only objection I can see to the general adoption of the plan is the expense. In Pittsburg natural gas was employed, a cheap fuel in that locality.

DR. LEE, of Pennsylvania: In the garbage crematory on Governor's Island the expense of operating is not as great as might be imagined. That crematory dries the garbage one day, and the next it is employed as fuel.

DR. J. B. HAMILTON, Surgeon-General U. S. Marine Hospital Service: In each family the means of cremating garbage exists. A garbage cart has not called at my house in several years, because all refuse is burnt in the kitchen fire. I do not believe an ordinance compelling this means of garbage disposal would be feasible, but think it might be accomplished through the authority vested in health officers. The improvements in the mechanical arts would justify the hope for the invention of a simple apparatus which could be employed in each house; something that would dry the garbage and then burn it. It seems to me that this plan of disposal is too generally neglected in household sanitation.

DR. LEE, of Pennsylvania: I know of several families who employ this plan, and I think it is more generally in use than is supposed.

DR. H. P. WALCOTT, of Massachusetts: I consider that Dr. Hamilton has more nearly hit the nail on the head than anyone. The object of the community is to do that which the individual cannot accomplish without unnecessary labor or expense on his part. It is for this reason that the combination of the efforts of many individuals constructs sewers and lays water pipes. But when it comes to garbage, each one has the means of

completely destroying it himself. When the impossibility of completely destroying the feces of typhoid fever, etc., by the means most commonly employed, even by bichloride of mercury, is considered, sanitary and health officers should bestow more attention on the only method which promises the successful attainment of this end, viz.: fire.

DR. ORME, of California: How can the garbage of cities be disposed of on a large scale?

DR. HAMILTON, U. S. Marine Hospital Service: It is only a question of combustion.

DR. ORME: Can health officers compel it? They might be able to do so in Eastern States, but this would not be possible in California.

DR. WALCOTT: It is a matter of experience. In the Eastern States health officers subject householders to much greater inconvenience. As, for instance, the requirements to keep the garbage in special receptacles; it is only removed at certain hours, it will not be removed if mixed with ashes, etc. If all these restrictions are successfully enforced, it would appear to be quite as feasible to require each householder to burn his own garbage.

DR. ORME: This question has caused a great deal of trouble in San Diego. What other cities have successfully employed cremation, and what are their crematories?

DR. LINDSLEY: Directions for reference to health authorities were given in his paper. They would undoubtedly supply all data.

DR. LEE: Dr. Walcott has suggested the idea of the household cremation of feces; this sounds repulsive—even impossible. But in my own household I had a patient, a young man suffering from melancholia. My family informed me he had not used the water-closet for several days. On inquiry I found he had cremated his feces in the stove.

DR. KENNEDY, Des Moines, Iowa: We have two garbage crematories in Des Moines in addition to those referred to by Dr. Lindsley. Dr. Turner has one in connection with his water-closet; all urine and feces go into it and are burned every ten days. One in the Capitol building is connected with the water-closet used by all the officers and employés in that building, and the matter is burned once a week. The odor is prevented by an inward draft from the seat of the closet. All gases and smoke generated in the weekly combustion are passed through a subsidiary fire and burned. One for dead animals is employed successfully. The expense is inconsiderable.

DR. LINDSLEY: In closing the discussion I would state that I simply brought it forward in order to secure the attention of physicians to this important question.

THE twenty universities of Germany conferred the degree of Doctor of Medicine on 847 candidates in 1886-87, as against 689 in 1885-86.

A CLINICAL STUDY OF THE SO-CALLED PRAIRIE ITCH, LUMBERMAN'S ITCH, ETC., WITH A CONSIDERATION AS TO ITS ENTITY.

Read in the Section on Dermatology, at the Thirty-ninth Annual Meeting of the American Medical Association, May, 1888.

BY WILLIAM T. CORLETT, M.D., L.R.C.P., LOND.
DERMATOLOGIST TO CHARITY AND ST. ALEXIS HOSPITAL, ETC.
CLEVELAND, OHIO.

From time to time one meets with reports in the medical press of unique forms of diseases of the skin closely allied in symptoms to scabies, yet it is claimed, differing therefrom in certain essential details. Nor is it confined to the medical press, but in medical societies and in the profession at large, there exists a firm belief in the entity of a disease, differently named in different localities, but all possessing four cardinal diagnostic points:

The first is *pruritis*, which is always present, but varies in intensity in different cases, in some it is continuous, while in others, there are periods of exacerbation, notably at the close of day.

The second symptom is objective, and consists in a *papillary eruption* which varies in distribution. The hands and forearms are most frequently affected, next in order the trunk and thighs, while the face does not always escape.

The third symptom, or more properly etiological feature, has been the *bête noire* of several amateur microscopists, who following the fashion of the time, have ascribed its *contagious* or *infectious* nature to an hitherto unlabeled parasite. A few years ago a graduating thesis was presented to an Ohio medical college on the bacillus of prairie itch.

The fourth and last distinguishing feature arises from the observation, that although resembling scabies, yet it *does not yield to the therapeutic measures best suited to that disease*.

It is well to bear in mind, that all cases of the so-called prairie itch do not present these four cardinal features, but one or more are present in every case.

In 1854, Dr. William Brodie, of Detroit, wrote a paper on "Prairie Itch," in which he disclaimed for it any relationship to scabies. If correctly informed, the honored ex-President of this Association still adheres to the precepts which were advanced when the dermatology of to-day was in its infancy, when the achievements of more modern dermo-pathological research were yet unknown, when the dermo-neuroses were not mentioned; and when the large family of lichens, which have since been largely eliminated and relegated to their natural places, were supposed to belong to a distinct inflammatory group.

In the winter of 1885, it was estimated that one person in every twenty in Louisville had the itch, and the time-honored remedy of hog's

lard and sulphur did not ameliorate the sufferings of the afflicted.

In writing of this, Dr. Hyde, of Chicago, says: Most probably the series of cold waves from the Manitoba region, which have lately been surpassing their usual limit, and reaching with unwonted severity some of the Southern States, has given rise to the itch in question.

In the *Kansas City Medical Index*, August Number, 1886, there appears an article entitled: "Is it Scabies?" The writer refers to the group of symptoms herein considered, and after quoting extensively, concludes by saying, that it is not scabies, neither is it a disease peculiar to this country. It is to be regretted, however, that the quotations do not inform us as to the means employed in eliminating the well-known disease of a like report, save in the positive assertions that the disease, in question, is not scabies, and that the observers have been in the continuous practice of medicine thirty, forty, and fifty years.

One exception, however, must not be omitted; Dr. Engstad, of Dakota, has made a careful microscopical investigation, and has not found the acarus—doubtless, in many cases of the so-called prairie itch Pasteur and Koch might do as much.

My attention was first directed to the "new itch" at the Ohio State Medical Society, in June, 1882, but a typical case was not met with until nearly five months later, at which time it was said to be epidemic in Portage and Wayne Counties, Ohio, and a committee was appointed from the North-eastern Medical Society to investigate the same.

The committee reported: The disease, for the most part, to be scabies due to the *acarus scabiei*.

In due time letters were received, stating that the treatment and hygienic measures suggested by the committee, had proven effectual in exterminating the epidemic.

In May, 1887, through the courtesy of the late Prof. A. B. Palmer, an opportunity was offered to investigate several cases of what was popularly known as the Michigan or Lumberman's Itch, then in the hospital of the University of Michigan.

Case 1.—Male, married, light hair, æt. 40, lumberman, complained of intolerable paroxysms of tingling and itching of variable duration, succeeded by intervals of quiet, which lasted sometimes weeks, sometimes months; during these intervals the subjective symptoms were entirely absent, and the lesions on the skin healed kindly.

Family History: His mother had suffered from neuralgia, and was, in the language of the patient, a nervous woman.

History of the Disease: It first appeared in the autumn of 1883. The season of the year had no appreciable effect on its course, but sudden changes of temperature, and the atmospheric conditions preceding a thunder storm were always

associated with an aggravation of the symptoms, and sometimes were sufficient to induce an attack. These attacks were ushered in by occasional shooting pains in the extremities, sometimes accompanied by a tingling sensation. Neither his wife nor children had contracted the disease.

Present Condition: The patient's general health is good; the eruption consists of irregularly shaped maculæ and vesicles of various sizes, in places grouped, but for the most part discreetly distributed. It is confined to the forearms, hands and legs. It is quite symmetrical and inclined to a linear distribution.

The case was regarded as a *neurosis cutanea*, having a certain resemblance—save in the exemption of the palms and soles—to the cheiropompholyx of Hutchinson, or to the dermatitis herpetiformis of Duhring.

Case 2.—Male, æt. 45, single, clerk, complained of an eruption which he had first noticed three years before. It consisted of small maculæ, having a dark punctate center, which had appeared on all parts of the body. Aside from the slight tingling and itching he felt little discomfort. Upon further investigation, the lesions were recognized as due to the *cimex lectularius*.

Case 3.—Female, single, æt. 30, teacher, of neurosthenic temperament. Complained of paroxysms of itching which appeared late in the afternoon, or upon retiring for the night. The family history is good.

History of the Disease: The itching began in the autumn of 1884, and disappeared in the following spring. At the next approach of cold weather it reappeared, and again disappeared the spring succeeding; in this way it has continued to the present. The patient sought medical aid, and was told that she had the Michigan itch. She slept with a sister without communicating it.

The present condition, both objectively and subjectively, is negative—the itching, since the moderation in atmospheric temperature having nearly subsided. The skin of the extremities is rough, with here and there a superficial cicatrix.

With this brief outline of the disease, it may be recognized as the *pruritus hiemalis* of Duhring.

Thus of the three representative cases of Michigan itch which, on account of their inveterate nature more than for any doubt as to diagnosis, were sent to the University of Michigan, not one belonged to other than well-known genera.

The two cases which follow occurred in private practice.

Case 4.—Male, married, æt. 46, clergyman, complained of an itching which gave him great annoyance. He was told by the physicians of his town that he had the new itch.

The history in brief is this: Four years ago, while engaged as a travelling preacher in Ver-

mont, he contracted an itchy disease of the skin, which, in due time, he gave to his six children—his wife escaped. The itching was most severe on the flexor surfaces, the hands were but little affected, and the face remained free. On the contrary, the children were first attacked on the hands.

At the time of examination the patient said he thought his disease had changed; he still complained of itching towards night-fall, but it appeared as distinct paroxysms aggravated by fatigue. The desire to scratch was irresistible, and unlike the condition preceding, it had once or twice suddenly disappeared for months, and as suddenly returned.

The present eruption too, unlike the permanent papillary rash of which he first complained, consists of whitish evanescent papules which tingle like the sting of nettles.

The children, he thought, had quite recovered.

This case is given because it brings out those points one is most frequently confronted with by the adherents of that unknown quantity—the new itch.

Thus the wife living in intimate family relationship did not contract the disease, because all are not equally susceptible to scabies any more than to variola, and bodily cleanliness may be effectually antagonistic. Later the primary disease became complicated with a neurosthenic element which, in turn, chanced to supplant it; but this may not prevent one from recognizing the first as most probably scabies, nor the second as lichen urticatus.

Case 5.—J. H., æt. 40, clergyman, complained of an itchy disease of the skin, for which he had been treated without avail.

Previous Condition: In 1870 he had what was probably eczema of the scalp, since which time his skin had given him no discomfort until six weeks ago, November, 1887, when he contracted an itchy disease from his children, they having taken it during the preceding summer while on a visit to Butler, Pa. The patient said, in the children the rash appeared first on the face, then on the body, and looked like measles.

Present Condition: The patient has a dry, rough skin, with a papular eruption, interspersed with a few small vesicles situated on the trunk and limbs; the hands and face are free. It is very itchy and prevents sleep. No acari could be found. The following day, at my request, the children were examined, and from the distinct burrows on the hands two acari were extracted, which confirmed the diagnosis of scabies.

Letters received from some of the medical gentlemen of Butler, informed me that the disease from which these children suffered was, at the time, epidemic in Butler County; that it was thought to be a new one; that its etiology and pathology were shrouded in mystery; but it was looked

upon as constitutional, and most probably contagious. It was said to yield to hydrargyri bichloridum, potassii iodidum, and solutio arsenicalis, Fowleri given internally variously combined; while acidum sulphuricum, zinci oxidum, and pix liquida, comprised the most reputed substances for external use. Woe betide the disease be it due to an inflammation, animal parasite or vegetable growth, that escapes this armamentarium.

Such a chain of evidence brought to light by this correspondence could not be withstood, accordingly the writer determined "to beard the lion in his den," and investigate the itch question of Western Pennsylvania.

Traces of the malady were heard of even before the confines of Ohio were passed, but not until Greenville was reached was a genuine case cited.

Case 6.—Was a lad who represented a household with scabies.

Case 7.—Eczema manuum.

Case 8.—Xeroderma.

Case 9.—Scabies.

At Meadville, of the several cases seen, but one will be given.

Case 10.—R. H., æt. 21, railroad employé, has had an itchy disease for a year, which prevented sleep. It has never invaded the face or hands; it was brought as one typical of prairie itch. Upon examination, he presented a papular eruption over the entire body with the exceptions cited; it was best marked on the flexor surfaces.

The patient said his hands were covered with oil while working, and he cleansed them with water and strong soap several times a day. Repeated efforts to find the *acarus scabiei* failed, but the papular lesions together with the history were sufficient, in the absence of more positive evidence, to warrant the diagnosis of scabies. The attending physician has since confirmed the diagnosis by letter, in which he says, the measures suggested at the time were effectual.

Oil City, Union City, and West Monterey, failed to satisfy the writer's desire for conquest or discovery.

Of the many cases that were collected at these places, suffice it to say, that they ranged from scabies to phtheiiriasis, from erythema simplex to eczema pustulosum, from pruritus to herpes, and from pityriasis to xeroderma.

It is not that scabies has disappeared with increasing civilization as one has said, neither is it that the classical description of Cazenave does not apply to the scabies of to-day, but rather it is that we lose sight of the clinical fact that the *acarus scabiei* is only a local irritant, inducing in one a papillary eruption, which in another is vesicular, while again in others, it may become pustular.

Frequent bathing, too, and other extraneous conditions, will place a limit to its local invasion; thus it is seldom seen on the hands of people who

frequently bathe, as in the last case cited, and among refiners of petroleum the hands and fore arms remain free.

In northern climates pruritus hiemalis often adds to the complication in diagnosis, which, in many cases, can be eliminated only by the clinical history.

Again, the senso-neuroses, which are becoming more and more apparent, often baffle the most skilled. But from the mass of cases which have been examined in these investigations it is apparent, that there exists no material to form a new disease, but an appalling need of a more thorough knowledge of those we already have.

143 Euclid Ave., Cleveland, Ohio.

MONSTROSITIES AND MATERNAL IMPRESSIONS.

BY R. B. JESSUP, JR., M.D.,
OF VINCENNES, IND.

Whether maternal impressions do or do not influence foetal development, is a question still before the profession. It is not my purpose to discuss this question, but simply to place on record two exceedingly interesting cases. Though we may not offer an explanation of maternal impressions, yet that is no argument against the existence of such influences. There is such a thing as establishing a fact by accumulated evidence; and should this contribution be the means of starting a series of well-authenticated reports, we might, ere long, point to the convincing evidence of maternal impressions.

The first case occurred in the practice of Dr. Ritter, of West Baden, Orange Co., Ind. The history is, briefly, as follows: The doctor was called, August 24, 1885, to a young woman, 22 years of age, a primipara, who had completed her seventh month of pregnancy. She was in heavy labor, which was terminated soon after his arrival. The child gave no sign of life at birth, but movements had been felt by the mother a few hours before labor began. The labor was perfectly normal, and the doctor, after much persuasion, secured the specimen. When seen by me it was splendidly preserved in a solution of alcohol, and is a perfect specimen of "frog-child," or anencephaloid monster. The doctor would not part with his specimen, but kindly allowed me to have it photographed, the views, in two positions, being shown.

The body is perfectly developed, and the limbs, in their minutest detail, are without defect. The eyes are prominent, as shown in the side view; the nasal bones, imperfectly developed, give a flattened appearance to the face. There is no evidence of cervical vertebrae; neither cerebellum nor cerebrum can be traced, but a flattened, hardened sac of what may have been serous fluid, fills the space from above the eye-brows to the shoulders. The skin is not developed beyond the su-

per-ciliary ridges, in front, and ceases at a point corresponding to the first dorsal vertebra posteriorly. If we complete the circumference by an irregular line passing above the ear on each side, we will include the surface not covered by skin.

This surface is well shown in the side view, and is occupied by the flattened, hardened sac, which may have been much reduced in size by the alcohol, but contains no structure, and seems to have been formed by the membranes of the brain. The portion of the surface not occupied by the sac is also covered by a membrane. The margin is covered throughout the circumference with a downy growth of hair.

Aside from the interest attaching to this rare pathological specimen, is the history, well authenticated, of the mother. In her early pregnancy she was fishing, and caught a frog on the hook. It had swallowed the hook in such a way as to make it impossible to extract it. She attempted to kill the frog by crushing its head with a stick. As soon as she saw the mutilated creature she became deathly sick, and for days sickened at the thought of it. Her offspring bore the marking of the mutilated frog, and the peculiar frog-face. There is no history of constitutional disease in either parent, and the mother has since borne two beautiful, perfect children. The cause of her miscarriage can not be explained, for she had been most careful during her pregnancy. The cause of the frog monster, marked by a mutilation, the sight of which had made the mother deathly sick, and the thought of which had sickened her for days, can not be explained. We can simply record the fact that a miscarriage did occur, and a frog-child was born, which is still preserved; and, though we may find no ex-

planation, until we do we shall believe this monster due to maternal impression.

The second case is as remarkable as the one recorded of Jacob and his method of producing striped cattle, by placing rods at their watering-troughs while the mothers were conceiving.

Mr. Wells, the president of the French Lick Springs Co., of French Lick, Orange Co., Ind., owns a valuable Morgan stallion, named Ethan, which is nine years old. While admiring this horse for the first time I asked the groom why he had whipped him so unmercifully; for along his sides were stripes, such as are made by a whip. He said the horse was born with those marks. A few questions excited my curiosity, and I sought Mr. Wells to get an intelligent and reliable account of this remarkable case. He said he had owned the horse since a colt, and knew positively that he was always so marked; that the markings had never changed, so far as he knew; there never had been any except on the sides; never any on the back, rump, neck, or under the belly.

He also said that the mother had been a pacer, on the track, for several years. That she was bred to a valuable Morgan stallion, and about the second month of her pregnancy the mare was entered in a race. She was known to be pregnant when she went in the race, but at the time it was not considered dangerous for the offspring. It was a very exciting race, and, to win a heat, the mare was whipped very hard on the last half mile. She was marked badly along the sides from the whipping. She was driven to a sulky, and the whipping was done, as it always is by jockies, along the sides, between the shoulder and hip, and above the sulky-shaft. This colt was born with these markings, and has had them since.

I examined the horse the next day. The markings cover a space, on right side, 36 inches long and 8 inches wide; on left side, 24 inches long and 6 inches wide. On rubbing the hand over the surface the ridges and hollows are felt, exactly like the welts from severe whip-strokes. These welts are most abundant on the sides, with an occasional one on the shoulder, none reaching so far forward as the collar mark, and none extending farther back than the flank. The welts are from one-fourth to three-fourths of an inch in width, and a few could be traced 20-22 inches in length. The spaces between the welts, over the ribs, where they are thickest, are from one-half to one inch in width; in places, however, they are so close as to make measurement almost impossible. Unfortunately, I did not secure a photograph of the horse, but he is there, serving in the stud at French Lick. None of his colts, so far as known, have ever been marked like him.

These cases may serve to strengthen the faith of those who believe in maternal impressions, or excite thoughtful consideration in those who would call them mere coincidences.

A CASE ILLUSTRATING THE EFFICIENCY OF DR. SENN'S HYDROGEN-GAS TEST FOR PERFORATION OF THE ALIMENTARY CANAL.

BY W. L. SCHENCK, M.D.,
OF OSAGE CITY, KAN.

Recognizing that whatever illustrates any new method in surgery is of advantage to the profession, I take pleasure in reporting the following case:

August 13, 8 P.M., I was called to see J. Williams, a strong man æt. 49 years, and City Marshal, who had been shot about two hours before. Dr. Shaw had previously reached the case and administered a full dose of morphine. Found the countenance anxious, breathing slightly accelerated and pulse 80, temperature not taken, but about normal, pain and jactitation considerable. The ball, from a 42-calibre pistol, struck the abdominal wall on a level with and 4 inches to the left of the umbilicus. There was considerable hæmorrhage but no escape of gas from the wound. The finger would not enter it, but the probe followed it for about 3 inches toward the umbilicus when, in the position the body occupied, it refused to go any further. While there was no special evidence of the bowels having been injured, we decided to insufflate with hydrogen gas. The urine drawn with the catheter gave no evidence of injury to the urinary organs. The bowels not having been moved for two days, large and repeated enemata of soap and water were administered, but with little result, no peristaltic action being excited and voluntary effort causing unendurable pain. Before we could complete our arrangement for the insufflation midnight came. The general condition of the patient seeming good, we decided rest for the remainder of the night would be better for him than an operation by lamplight. Administering $\frac{1}{2}$ grain of sulph. morph. and $\frac{1}{10}$ gr. of sulph. atrop. hypodermically and leaving morphine to be given *pro re nata*, we adjourned until 9 A.M.

August 14, 9 A.M. The patient had had a quiet sleep and, though the countenance was anxious, the face pallid, the breathing hurried and the pulse 120 and quite compressible, he was cheerful and courageous.

In a few moments we were ready to insufflate and, if need be, to operate—Dr. J. M. Heller to administer chloroform, H. C. Galliher, chemist, to attend to the gas, and Dr. Schenck, assisted by Dr. Shaw, to use the knife. At this juncture, alas! the man of the law came upon the scene to prepare for a post-mortem by an ante-mortem examination. Encouraging the patient with the thought that the operation might prove fatal, he proceeded to take his testimony. We waited impatiently until 10:30, when, with greatly increased exhaustion, after a full dose of brandy, the patient

went kindly under the influence of chloroform and ether aa, and the hydrogen gas was soon traversing the rectum, descending, transverse and ascending colon. At the ileo-cæcal valve there was a slight gurgling sound followed by a tremulous movement, which was very soon transferred to the track of the ball through the abdominal wall, and in a moment the diagnostic flame told the tale of a perforated bowel. The bladder was emptied, the abdomen shaved and washed with an antiseptic solution, and at 11 o'clock an opening made from a little above the pubic bone to 2 inches above the umbilicus, and very soon an opening was found in the ileum 3 feet from its cæcal terminus. The edges of the opening were trimmed and it was closed with Gely's suture. Six inches nearer the ileo-cæcal valve the ball passed through the gut, its exit making a wound $\frac{1}{2}$ inch in length. The edges of these wounds were trimmed and closed with a continuous suture. Four inches further up the bowel there was a solution of continuity in its peritoneal and muscular coats. These were brought together with a few stitches and, there being no other wounds near except a perforation through the mesentery, the gas was again injected, when other openings were quickly demonstrated. Twenty inches further up the bowel was a hole in the bowel near its mesenteric attachment. This being closed, it was found that a little further on the ball had again passed through the bowel, one opening being an inch in length, and the space between the openings very narrow. This was closed by folding in the peritoneal coat and making the cuff suture with a continuous stitch, trusting to adhesion of the serous surfaces and the sloughing away of the intervening portion. The last perforations were double ragged wounds extending to within $\frac{1}{4}$ inch of the cæcum. Another injection of the gas proved all the openings, nine in number, closed. The bullet passed thence behind the cæcum, bruising it as it passed, and entered the crest of the ileum $\frac{1}{2}$ inch beneath its superior border. Either the twisted position of the body when the shot was received had lifted up the colon, or it was congenitally higher than is supposed to be normal.

During the operation the bowels were kept covered with a warm solution of boracic acid, and the cavity was well sponged and washed with solutions of the acid and of bichloride of mercury. The external opening was closed, with a drainage-tube at its lower angle, the suture dusted with iodoform, covered with a pad of absorbent cotton saturated with a 5 per cent. solution of boracic acid and kept in place by a broad flannel bandage. The patient had been on the table three and one-half hours, the latter part of the time but slightly under the influence of the anæsthetic, and was nearly pulseless. Hypodermic injections of brandy and, as soon as possible, brandy and ammonia by mouth, were administered. Slight reaction occur-

ing, he was wrapped in warm blankets and removed from the operating-table, but at 4 o'clock he sank rapidly and expired.

At 7 P.M. Dr. Slaw and myself made a legal autopsy, and found the ball had passed obliquely through the abdominal wall, as indicated in the diagnosis, entering the cavity $\frac{1}{2}$ inch from the umbilicus, passing through the bowels with a very slight downward obliquity, injuring them as already stated, and imbedding itself in the ileum near its superior border. No further injury to the bowel was discovered, and the cavity of the abdomen was found well cleansed.

Whilst this case proved fatal from the extent of injury to the bowels, it admirably illustrated the efficiency of Dr. Senn's method of diagnosis. The apparent direction of the ball left room for questioning whether it had dipped deeply enough into the abdominal cavity to reach the bowels, and the general condition of the patient did not solve the doubt, while the insufflated gas quickly told the tale.

MEDICAL PROGRESS.

LOCAL ANÆSTHETIC EFFECTS OF HELLEBOREIN.—V. VENTURINI and E. GASPARINI, working in the laboratory of Professor Buffalini, at Siena, recently made the discovery that helleborein had a local anæsthetic effect. A communication on the subject was made on March 9 by Prof. Buffalini to the Società tra i Cultori delle Scienze Mediche, of Siena. The physiological effects of helleborein and helleborin were already partly known by the experiments of Schroff, Dragendorff, Marmé, Santoliquido and Paul. Santoliquido recently contemplated an investigation of the influence of these two glycosides on the heart. The local anæsthetic effects of these two substances, however, had been quite unknown hitherto. The following is a summary of the observations of Venturini and Gasparini: On the instillation of some drops of a solution of helleborein into the conjunctival sac of rabbits, complete anæsthesia of the cornea came on after fifteen minutes. Pricking with a needle was not felt by the animals. The same results were also obtained in experiments on dogs, without any interference with the function of the pupils or eyelids or with vision. The experiments were then repeated with a solution each drop of which contained about 0.0005 grams of the glycoside; the same anæsthetic effect was produced on the cornea after an interval of fifteen minutes, when 3 or 4 drops of this strength were injected into the eye. The cornea regained its normal sensibility in half an hour from the commencement of anæsthesia. No bad after-effects were observed on the subsequent days. Venturini and Gasparini consider that, in operations on the eye, helleborein is pref-

erable to cocaine, as its effect is limited to the cornea, and does not affect the sensibility of the other parts of the eye in any way. They conclude that: 1. Helleborein, even in a very diluted solution, produces complete anæsthesia of the cornea, without irritating the conjunctiva or the cornea. The anæsthesia produced by this substance is of longer duration than that obtained with cocaine. 2. Though the anæsthesia is complete, there is no relaxation of the eyelids. 3. No change in the pupil or in the intraocular tension is observed. 4. Helleborein causes local anæsthesia in the parts into which it is injected. As, however, it has a powerful cardio-toxic effect, its application to the cardiac region requires great precaution. Whether the influence of the helleborein is to be ascribed to the helleborin (as Professor Buffalini thinks) has yet to be decided.—*British Medical Journal*, August 4, 1888.

ELECTRICITY vs. LAPAROTOMY IN INFLAMMATORY AFFECTIONS OF THE UTERINE APPENDAGES.—DR. EGBERT H. GRANDIN, of New York, says:

The class of cases in which I would contend electricity will prove as serviceable, and frequently more so, than laparotomy; and this, too, without subjecting the woman to the slightest risk, are those in which careful exploration, if necessary under anæsthesia, fails to suggest the presence of pyosalpinx. Disease of this nature calls for speedy and radical action. The knife is here indicated, even as it is in any other region of the body where pus is predicated. A history of recurrent attacks of pelvic peritonitis should constitute the call for laparotomy, lest the next attack should eventuate in a general peritonitis fatal to the patient. Where, however, the careful bimanual exploration of the patient, the rational history and the appearance do not suggest the likelihood of pyosalpingitis, then the greatest palliation, if not entire cure, may be predicated from resort to electricity. The conditions termed catarrhal salpingitis, pachysalpingitis, perisalpingitis, perioophoritis, I would include in the class which may properly be subjected to electricity rather than to the knife.

When I first began to systematically use electricity in my gynecological practice, I deemed it contraindicated in acute pelvic peritonitis—the term under which, for the sake of brevity, I would include the affections just referred to—and to be used with caution in subacute instances. With increased experience I have learned that the agent may not alone be resorted to with safety, but with benefit as well, where the condition is acute. By means of electricity the circulation is regulated, absorption is favored, and we effectively counter-irritate. The technique of the application I have so recently described that it is unnecessary here to do more than lay stress on certain of the cardinal

principles. Notwithstanding the advocacy of Apostoli, Engelmann, and others, I am not convinced that it is at all essential to success to use currents of great intensity. Indeed, in certain instances, I am satisfied that I obtain greater benefit through resort to weak currents of considerable duration. The action of the current is thus more prolonged, and the effect more lasting. The non-active pole, and this will ordinarily be the negative pole, should cover as large a surface as possible, the abdomen being the preferable site for its application. As long as there exists tenderness on pressing the vaginal vault, or pain in imparting motion to the uterus, galvanism is indicated, the positive—the anæsthetic, alterative pole being placed within the vagina. When the symptoms have disappeared, faradization, first the primary current, and later the secondary, will be found most effectual in completing the cure in so far as this is possible. In the intervals between the séances, and these should be held every other day, at the outset, the uterus should be gently supported by a wool tampon—the organ should not be crowded up by a number of tampons packed as solidly as possible into the vagina, for thus as much harm is done to the ligaments, blood-vessels, and adjacent organs in an upward direction as they suffer when, without the tampon, the uterus sags downward. Attention to these simple rules is strictly essential to success. Through resort to electricity the gynecologist may not gain such great renown as the operator who can boast of a long series of operations, and who can exhibit to colleagues and to patients the bottled specimens, emblems of his prowess, but he will have the satisfaction—no mean one—of knowing that he has relieved suffering without risking life, and he will find that a reputation for conservatism bears golden fruit in plenteous harvest.—*Medical Record*, August 25, 1888.

CAN THE MOTOR AREA BE REMOVED IN LARGE PIECES WITH IMMUNITY FROM SERIOUS CONSEQUENCES?—In his Address at the recent annual meeting of the British Medical Association, DR. WM. MACEWEN said: If this region be of such psychical importance to movement, and destructive cortical lesions in it are followed by secondary degeneration of the motor tracts, then excision of these areas will necessarily induce permanent paralysis, late rigidity, and ultimate structural contraction. The removal of large wedges from the brain, especially in the motor centres, will induce serious effects upon the brain as a whole, causing, during cicatrization, a dragging and displacement of the neighboring parts, with final anchoring of the cerebrum to the cicatrix. In an acute ulcerative process rapidly advancing, such as an abscess, none can hesitate to evacuate the pus; it is not the living brain-substance which is removed, but the peccant matter alone. Epilepsy presents

quite another aspect. In the presence of a stationary cicatrix, or of a slow-growing neoplasm in the motor area, occasionally producing fits, few would attempt the removal of such a large wedge of the motor region as to induce permanent hemiplegia. Even when the fits are much more numerous and aggravated, it is serious to contemplate the production of hemiplegia while attempting the cure of the fits. No doubt these epilepsies, when long continued, especially in early life, are apt to lead to great and extensive instability of the motor cortex, so as to warp the whole cerebral function, and ultimately involve life itself. Still, how much better is the cure by the removal of a large wedge, involving the greater part of the motor area? How many people would submit to have their upper and lower limbs, on the same side of the body, amputated by disarticulation at their proximal joints—for this is what the hemiplegia amounts to—in the process of cure of their fits? Numerous epileptics have been asked the question by me, but none have expressed their willingness to undergo such a cure. Even had they done so, the circumstances would require to have been exceptional to have induced one to hazard the life of the patient for so poor a result. It is true that corresponding wedges have been removed from the brain of monkeys, and these animals have survived for months thereafter. In men also they have been removed by others; in one instance reported to me the patient remained completely hemiplegic until his death some months after. Nor is the removal of very large tumors and large wedges of brain free from immediate peril to life. In several instances operated on elsewhere, death has ensued—one while the tumor was being removed from the brain, and one immediately after the completion of the operation.

In cerebral surgery, not only does one require to localize the lesion, and to select suitable cases, but also, after exposing the brain and its lesion, to judge when to advance and when to hold the hand. In a case rightly localized from the motor symptoms, a tumor was exposed in the leg and arm centres, on the left side of the brain; but its dimensions were such as to cause me, after carefully contemplating them, to refrain from removing it, as it would have led to a hemiplegia of a much more pronounced character than was present. Instead, the vessels which supplied it with nutriment and which ran into its substance, from the surface, were all ligatured, in the hope that this would effect a restraining influence on its growth. The patient recovered and is considerably improved. Though the fits are not quite cured, they are not so severe as formerly, and are somewhat altered in character.—*British Medical Journal*, August 11, 1888.

THE PHYSIOLOGICAL ACTION OF ONOBAIO has

been investigated by MM. HENRY DE VARIGNY and PAUL LANGLOIS. Onobaio is an arrow poison used by the natives of Oboko in the form of a hard resinous ball. A 1 per cent. solution was made with some of these balls. It was found that injections of 5 or 10 milligrammes of this solution kills rabbits and guinea-pigs very quickly. The animal is bent double; it leaps about, then falls over on its side, making efforts to breathe, and dies with well-marked symptoms of asphyxia. If the animal is then opened the heart will be found to be perfectly still. The ventricles no longer beat; a slight action is still observed in the auricles. The lungs are pale and anæmic. During life no disturbance of motor power or of sensibility is observed. One or two milligrammes were injected under the skin of a frog in which the heart had been laid bare. After a few minutes it was found that the ventricle became contracted after auricular systole; this phenomena increased: four or five minutes after the injection the quantity of blood entering the ventricle at each auricular systole became infinitesimal, and finally none passed in. The ventricle ceased to act; the auricles continued to contract for ten to fifty minutes. The following experiments were made upon dogs which had been subjected to the action of chloral and curare. In one case a large dose (1 centigramme of onobaio in 1 cubic centimetre of water, injected in about a minute) caused cardiac disturbance, without any definite respiratory symptoms. To avoid the direct action of the poison on the endocardium a solution of 1 milligramme in 1 cubic centimetre of water was injected into the veins at intervals. In the case of weak doses (4 millig. to 13 pounds of the animal's weight) the breathing became much slower a minute or two after the injections. This phenomena, which was not accompanied by notable cardiac disturbances, lasted one or two minutes, and then ceased. Larger doses (8 milligrammes to 11 pounds of weight, administered in four injections in about half an hour) quickened the breathing for a few instants. The breathing then became gradually slower, and at the end of two or three minutes entirely ceased. The heart continued to beat, but subsequently became slower, and finally ceased. In an experiment with 6 milligrammes to 11 pounds of the weight the cessation of the respiration did not arrest the action of the heart. Artificial respiration was practiced; the heart continued to beat, and at the end of a few minutes the respiration became natural. Onobaio sometimes causes vomiting in animals which have not been previously brought under the influence of chloral.—*British Medical Journal*, June 30, 1888.

NAPHTHALIN IN PLACE OF ARSENIC AS AN INSECTICIDE.—HAGER calls attention to the dangers attending the use of arsenic and its prepara-

tions as an antiparasite and vermin-killer. He strongly recommends to use naphthalin whenever arsenic would be indicated for the above purposes. He gives, among others, the following formula:

Naphthalin	40 parts.
Chloroform	80 "
Benzine	100 "

℞.

Heat carefully to about 20° C., and agitate till the naphthalin is dissolved. American petroleum may be substituted for the benzine. These solutions may be applied as they are to the skin of animals infested with vermin, or they may be applied in a diluted state. The naphthalin may be incorporated with vaseline if an ointment is desired for use, or if an oily liquid is wanted the above solutions may be mixed with liquid vaseline in the proportion of 200 of the former to 1,200 of the latter. Hager also speaks highly of the infusion of quassia as an antiparasitic application.—*Pharmaceutical Record*, May 15, 1888.

SALT IN THE SICKNESS OF PREGNANCY.—In a recent number of the *Medical Press* DR. GREENE records two cases of sickness of pregnancy treated successfully with common salt. In the first case the salt was given in 5 grain doses in 1 ounce of chloroform water. The sickness lessened after the first dose, and ceased entirely when six doses had been given. The medicine was continued three times a day until the end of gestation. In the second case the same result was obtained. The action of the salt in these cases may have been due to its antacid properties; in both cases the secretions were very acid, but soda, potash, and ammonia had no good effect. Dr. Green suggests that, as some patients might think the remedy too simple, it should be prescribed by its clinical name—chloride of sodium.

SUBSTITUTE FOR MILK IN INFANTILE CHOLERA.—TEDESCHI recommends the following as a substitute for cow's milk:

White of eggs	15 grains.
Oil of sweet almonds	35 "
Sugar of milk	40 "
Carbonate of soda	0.40 gram.
Common salt	0.20 "
Neutral phosphate of lime	2.50 grams.
Water	1 litre.

Make an emulsion.

PILLS FOR COUGH IN EMPHYSEMA AND CHRONIC BRONCHITIS.—The following pills were used by the late GUÉNEAU DE MUSSY:

Purified tar	2 grams.
Dover's powder	3 grams.
Powdered benzoin, q. s.	

Make 40 pills.

S. Take 2 to 6 pills daily.

SATURDAY, OCTOBER 13, 1888.

THE STUDY OF DISEASES OF CHILDREN.

At the recent annual meeting of the British Medical Association DR. W. B. CHEADLE, President of the Section of Diseases of Children, took as the subject of his address "The Present Position of the Study of Diseases of Children in Relation to Medical Education." This address is at once instructive and suggestive.

Dr. Cheadle doubts the wisdom or propriety of elevating diseases of children into a specialty—of separating them from the general study of medicine and surgery. Art is still too narrow, and human wit too broad to make such a specialty, Dr. Cheadle thinks; and but for the larger experience at the great general hospitals our knowledge of childrens' diseases would be much less. Doubtless there are very many that will not share this opinion. Still, the fact remains that in medical education the vast importance of the thorough study of disease as seen in children is but imperfectly realized. While it may be true that a specialty of diseases of children is unnecessary, special study of diseases of children is necessary. General practitioners form the bulk of the profession, and the majority of their patients are children, whose bodies are peculiarly susceptible to diseases and treatment, their diseases requiring a nicety of discrimination and a delicacy of skill in management beyond what is required in adult cases. As a rule,

too, many of the disorders of early life require immediate treatment; and to wait for the specialist is to lose time.

"The death rate of children is almost ten times as great as of adults; and yet to fight against this we are content to send out our students unpracticed, inexperienced and untaught." This, says Dr. Cheadle, is a serious blot upon our system of medical education. Almost forty years ago Dr. Latham, Sir Thomas Watson and others, pointed out the very defective condition of knowledge with regard to diseases of children, and insisted on the urgent necessity of more adequate provision for instruction in the subject. Dr. Cheadle fears that the situation is very much to-day what it was then—and he speaks as whilom dean of a medical school, as physician to a general hospital as well as one for children, and as an examiner in medicine for about ten years. As an examiner he has always made it a point to set questions in diseases of children, and his uniform accumulated and accumulating experience is that the candidates, as a rule, are lamentably ignorant of this subject. Many of them are destitute of any clinical experience of the common diseases of infancy. It is a fact, and certainly one to be deplored, that many general practitioners dread to be called upon to treat a sick child; they find extreme difficulty in making any clear diagnosis; and many treat all little children on "general principles," as though all children were alike.

As a matter of fact, the practitioners that treat children skilfully and on scientific principles, have for the most part learned what they know after graduation. Some hospitals, as we know, do not receive children of less than 2 years of age, except in special and urgent cases. But it is in the first two years of life that we mostly encounter the diseases distinctive of infancy and childhood. This is the period in which the congenital faults of structure and of inherited disease manifest themselves, and when the troubles of feeding and dentition, with their consequences, occur.

In the way of reform Dr. Cheadle suggests:

1. That the examining bodies make it clear that a competent knowledge of diseases of children will be required of candidates in their final examinations.
2. That they also require, as a part of hospital practice, an attendance of three months on a course of clinical instruction in diseases of children, which shall include those of early in-

fancy, at either a general or special hospital. 3. That children under 2 years of age be admitted freely to the childrens' wards of general hospitals and to special hospitals. 4. That an organized system of instruction, both practical clinical instruction and lectures, be introduced at each medical school.

Since a very large proportion of the patients of the general practitioner are children, and seeing that infant mortality is so much greater than adult mortality, no argument is required to show that medical students should receive adequate instruction in diseases of children, and that they should be thoroughly examined as to their competency to diagnose these diseases and treat them.

The defective education in diseases of children by the medical colleges and hospitals of Great Britain as represented by Dr. Cheadle, certainly does not exist to the same extent in this country. A very large proportion of our medical schools have a professorship of diseases of children filled by an active and efficient teacher, and with which he connects one or two clinics each week in the childrens' department of a hospital or dispensary, to the latter of which especially, children of all ages have access. And attention to the instruction in this department is as obligatory upon the medical students as to that in any other department of the college curriculum.

CAUTION IN RECTAL INSUFFLATION WITH HYDROGEN GAS.

Senn's paper, entitled, "Rectal Insufflation of Hydrogen Gas, an Infallible Test in the Diagnosis of Visceral Injury of the Gastro-intestinal Canal in Penetrating Wounds of the Abdomen," received merited attention, at the time of its presentation before the Section on Surgery, at the last meeting of the American Medical Association.¹ Since the publication of this remarkable essay, numerous cases, illustrative of the procedure, have appeared in various home journals. Dr. W. L. Schenck, of Osage City, Kansas, reports a case of interest in this connection, that appears elsewhere in the columns of the present issue of THE JOURNAL.

As yet, no untoward results have been recorded, and the belief is general that the method is totally

devoid of risk. This impression, however, is erroneous. There are at least two possible sources of danger in the use, or rather misuse, of the plan that deserve serious consideration. As at present informed, these items have received adequate attention neither in the original paper, nor in later discussions of the procedure. It is the purpose of this note not to enter into a criticism of Senn's really brilliant effort, but merely to mention certain precautions, that are at once simple, rational and necessary.

In so far as rectal insufflation with hydrogen gas is a problem in chemistry, it postulates chemically pure hydrogen, and absolute freedom from atmospheric air. Now, it is apparent that these two conditions may not always be supplied with ease. As the difficulties in the practical details of the method appeal most directly to the chemist, we have sought responsible opinion from an eminent professional source. In reply to our inquiry, a distinguished teacher of chemistry writes:

"I believe Professor Senn, himself, says that he has never seen any bad effects result from the use of the gas, and I have no doubt that in skilful hands, such as his, there would probably never be any danger in its employment. But I can readily imagine that a careless and inexperienced operator might meet with unhappy results in at least two ways:

"I. Unless the hydrogen were generated from perfectly pure material, it might contain impurities of greater or less toxic power. The most dangerous of these would be hydrogen arsenide (arseniuretted hydrogen), which is one of the most powerful poisons with which we are acquainted when inhaled into the lungs, and *presumably* quite dangerous, also, when injected into the bowels. Since both sulphuric acid and zinc, as ordinarily found in commerce, are usually considerably contaminated with arsenic, the hydrogen given off from such material would be quite rich in the poisonous hydrogen arsenide. Professor Senn directs that pure zinc and acid be used; but a careless operator might forget or neglect this and use commercial material, with results that I fear would be exceedingly unpleasant, if not dangerous.

"II. There is certainly danger of getting a mixture of atmospheric air with the hydrogen, either by faulty generation or by unskilful manipulation during insufflation. In that case, an

¹ THE JOURNAL, June 23d and 30th. Vol. x, Nos. 25 and 26.

explosion would be likely to occur, upon applying a light, which might do considerable damage. Care, however, could remove this danger wholly, for a skilful operator would assure himself of the purity of his hydrogen before using it, nor would he permit it to become contaminated during use. As there is but a very small amount of oxygen in the intestinal gases,² I think there would be no danger of an explosive mixture being formed after insufflation of a pure gas.

"I think we may conclude, therefore, that Professor Senn's method is entirely destitute of danger in careful hands; but if unskilfully employed we might very possibly have bad results either from a poisonous gas, or from an explosive admixture of air. This, however, does not detract from the value of the procedure, for scarcely any operation in surgery is safe unless carefully conducted."

THE MEDICAL EXAMINING BOARD OF VIRGINIA.

A few weeks ago we called attention in *THE JOURNAL*, to the excellent work that has been done by this Board, showing from the work that boards of examiners like the Virginia Board are a necessity for the protection of the public from incompetent practitioners. We need not again go over the ground covered by that editorial article. The readers of *THE JOURNAL* will remember that the editorial in question was favorably commented on in our pages by so excellent a teacher and so learned a physician as PROFESSOR WILLIAM OSLER, of Philadelphia, who, though a graduate of a Canadian school is now a teacher in one of the high-class medical schools in the United States.

It will be remembered that we said in our editorial article that the opponents of the Medical Examining Board of Virginia were made up chiefly of the teachers in the Medical College of Virginia, and the students of that college; and that the reason for their opposition is the fact that the Medical Examining Board of Virginia has shown conclusively that the Medical College of Virginia—with some other colleges in the country—is not doing creditable work. We pointed out that the remedy for colleges, whose students have not stood well before the Virginia Board, is in their own hands. If they will teach

their students as they should be taught there would and could be no complaints.

It seems, however, that the teachers in the Medical College of Virginia, and a few who sympathize with them, prefer to remedy (?) the matter in another way. The Medical Society of Virginia meets in about a week, and the teachers in the Medical College of Virginia will go to Norfolk for the avowed purpose of "ousting" the present members of the Board. Perhaps they have some of their sympathizers that they wish to elect or have elected members of the Board by the Medical Society of Virginia. With some knowledge of the *personnel* of the Virginia Society we do not for a moment believe that they will put out of office men who have done their duty, and their whole duty in so far as they could, to the profession and the people of Virginia. By doing this the Medical Society of Virginia would declare practically in favor of a low standard of medical education—and we do not for a moment believe that the Society will do this.

Some of the teachers in the Medical College of Virginia, and their friends, have said that the recent editorial in question was written by members of the Medical Examining Board of Virginia, or that it was written in Richmond. Some of them claim to recognize "Richmond ear-marks." The editorial was written in Chicago, by a regular editorial writer of *THE JOURNAL*, and the sole basis of the editorial was the last report of the Medical Examining Board of Virginia. It was written by a disinterested person, and, so far as the particular Board and State are concerned, from disinterested motives. The sole motive in writing the article was to show what a good Examining Board could accomplish in the way of protecting the public against badly taught and incompetent graduates of schools that do not do good work. We were convinced when the editorial was written that we were in the right, and subsequent events have shown that we were right. We were convinced that the Virginia Examining Board was and is doing good work, and we are still convinced of it after looking into the matter more closely. We were equally convinced that the Medical College of Virginia—and other colleges mentioned—were doing bad work; and of this we are still convinced. And this conviction is strengthened by the attempt to be made at Norfolk to remove honest workers from the Board.

²Gautier, *Chimie appliquée à la physiologie, à la pathologie*, etc., vol. i, p. 426.

We hope the Medical Society of Virginia will not be guided by a few men who wish to cover up their bad work. Will the teachers in the Medical College of Virginia openly acknowledge that their work is bad, and their graduates incompetent to practice medicine, by attacking the Board? We hope not. Would it not be better for themselves, for the college, for the profession of the State, and for the public, if they would resolve to teach their students so that they may take equal rank with the graduates of the University of Virginia? Do the students of the Medical College of Virginia wish, on the plea of ignorance and incompetency, to be admitted to practice without examination? That is what their petition to the Virginia Legislature last winter amounted to. Will they not rather demand of their teachers that they place them on equality with all other students and graduates, by instructing them so that they shall be competent practitioners of medicine. The remedy, as we said before, is in the hands of the colleges, not the Legislatures. The Virginia Legislature may grant the degree of Doctor of Philosophy to every graduate of the Medical College of Virginia; but that will not make them philosophers. It may enact that each of those graduates is learned in medicine; but that will not add anything if their teaching has been such that they cannot pass the examination of the State Board. No one can be made moral by act of Parliament—and no Legislature can enact a knowledge of medicine into the mind of any student. As we know the tree by its fruit, we know the college by its graduates. "A fair field and no favors" is all that any competent man wishes.

TRANSACTIONS OF THE NINTH INTERNATIONAL MEDICAL CONGRESS.

The full proceedings, addresses, papers and discussions of the International Medical Congress at Washington, September, 1887, have been published and distributed to the members and others who were entitled to copies; making five royal octavo volumes of over 760 pages each, an aggregate of 3,800 pages, and about 600 illustrations. The Transactions of the great International Medical Congress at London, in August, 1881, are comprised in four royal octavo volumes averaging 638 pages, an aggregate of 2,552 pages and 180 illustrations.

It will be seen that the Transactions of the Washington Congress contain nearly one-third more printed matter and three times as many illustrations as those of the London Congress. For style of printing, quality of illustration, and we may venture to add for value of matter, they will bear favorable comparison with the Transactions of any one of the preceding International Medical Congresses. Much credit is due to ex-Secretary-General Hamilton and his assistants for the expeditious and excellent manner in which they have executed their laborious task.

EDITORIAL NOTES.

DEATH FROM CARBOLIC ACID.—At Milton, Ohio, on October 6, a 3-year old child secured a bottle of carbolic acid and a teaspoon, and began feeding it to the baby brother in the cradle. The screams of the baby attracted the mother, who was outside, and when she reached its side it was gasping for breath and died in a few minutes. It seems almost incredible that anyone having any business with carbolic acid could be so criminally careless as to leave the poison within reach of a child.

LARGE INTESTINAL DIVERTICULUM.—In the *Centralblatt für Gynäkologie*, No. 17, 1888, MAAS, of Würzburg, reports the case of a boy, æt. 14 years, whose abdomen began to enlarge soon after birth, and continued to enlarge until a year before the lad came under treatment. It then became much larger, and the boy had dyspnoea and palpitations. The bowels moved frequently, but the stools were scanty and thin. The abdominal walls were very tense, though not cedematous. The urine was normal; the skin pale; some subcutaneous veins were uniformly dilated. The abdomen measured 35.5 inches at the umbilicus, and 3 inches higher the circumference was 39 inches. There was uniform tympanitic resonance, and the lateral impairment was slight. No solid tumor could be detected. An enema was given, and much faecal matter was passed. When a sound was passed into the rectum it could be felt apparently over the tumor, under the parietes, and hence a diagnosis was made of congenital hydro-nephrosis on the left side, or cystic degeneration of the kidney. An exploratory puncture in the left loin with a large trocar allowed some feces to

escape, and an incision was then made along the linea alba. The surface of the tumor was covered by a large plexus of veins. The operators feared to proceed, and the abdominal wound was closed. There was no subsequent peritonitis; but a sudden increase of the swelling was followed by intense dyspnoea, and this by sudden death. The autopsy showed that the tumor was an immense diverticulum from the upper part of the rectum, containing some gas and 14 litres of thin fæces. The communication with the rectum was at the posterior inferior part of the pouch. The rectum was strongly compressed by the tumor. Kölliker and Maas attribute the diverticulum to a disturbance of the normal involution of the blastodermic layers.

SOCIETY PROCEEDINGS.

American Surgical Association.

Annual Meeting, held in the Main Hall, Grand Army Building, Washington, D. C., September 18, 19, 20, 1888.

(Continued from p. 499.)

TUESDAY, FIRST DAY—AFTERNOON SESSION.

DR. W. W. KEEN, of Philadelphia, read a paper on

THREE SUCCESSFUL CASES OF CEREBRAL SURGERY,

including: 1. The removal of a large intracranial fibroma. 2. Exsection of damaged brain tissue. 3. Exsection of the cerebral centre for the left hand.

Case 1.—Large tumor in the cerebrum, probably arising from an injury at the age of 3 years; tumor removed at 27; hernia cerebri; recovery.

The patient, a young man of 27, at 3 years of age fell, striking his head on some bricks. At 5 he had measles followed by discharge from the right ear, impairing hearing. In February, 1885, epilepsy supervened, with intense pain in the head. About April right-sided hemiplegia was complete, with aphasia. Right pupil was largely dilated and irresponsive to light; vision imperfect.

When first examined by Dr. Keen the only remnant of his former condition was epilepsy, hesitation of speech and headache. In the attacks the head and neck were turned to the left, while the body was turned to the right. Convulsions general. Right pupil larger than left. A small scar was decided on as that resulting from the accident. This was $\frac{1}{2}$ inch above and in front

of the left superior stephanion, $2\frac{1}{4}$ inches to the left of the middle line, and 3 inches behind the external angular process. The temperature on the left side of head was 1° higher than on the right. Dynamometer recorded right 30° , left 35° . Left knee jerks normal, right subnormal. Diagnosis, probable tumor at the base of the frontal convolutions, involving the centres for the leg, arm, face and speech.

The operation was performed December 15, 1887. A $7\frac{1}{2}$ inch trephine was applied over the seat of the scar. This opening was enlarged 3 inches. A tumor was discovered and removed. It weighed 3 ozs. 49 grs. Its size was $2\frac{7}{8} \times 2\frac{1}{2} \times 1\frac{3}{4}$ inches. Hæmorrhage was abundant and checked with difficulty. The wound was dressed antiseptically, drainage being provided for. The wound was followed by hernia cerebri. This showing no tendency to cicatrize, thirty-four skin grafts were applied. In ten weeks cicatrization was complete. The elevation was then followed by a concavity. The tumor proved to be a fibroma, a rare form of intracranial tumor.

Case 2.—Simple depressed fracture followed in four months by epilepsy; thirteen months later trephinement and removal of damaged brain tissue; recovery in seven days; cure of epilepsy to date. Young man 25 years of age. In November, 1886, he fell nine feet, receiving a severe blow on the right side of the head. He was unconscious for a considerable time. There was temporary loss of feeling in the three left ulnar fingers. On tapping the head on the right side he produced a "cracked pot" sound. Epilepsy began in March, 1887. Up to April he had had five positive attacks. The diagnosis was traumatic epilepsy from depressed fracture, centre for left hand and supramarginal gyrus involved. Operation was done April 12, 1888. As soon as the flap was raised the bone was found to be splintered. A $1\frac{1}{2}$ inch disc of bone was removed. The dura mater had been ruptured. A small piece of bone had been forced through the dura mater and had become adherent to its under surface. The brain substance had also been ruptured. A cyst $\frac{1}{4}$ inch in diameter was found connected with the piece of bone. All of the brain substance that was altered in character was removed. This piece was $\frac{1}{4}$ inch long by $\frac{3}{4}$ inch in width. The button of bone was perforated and attached with chromic catgut to the flap, so that the bone could not fall in upon the brain substance.

The wound was healed in seven days. After the operation there was paralysis of the hand as regards flexion. That night flexion was recovered.

Note made May 28, 1888, shows that the disc of bone is adherent, mental and physical condition excellent, flexion of fingers normal. The iris of the right eye, twenty-four hours after the operation, responded separately as well as its fellow. This isolated symptom of want of proper

reaction of the right iris is probably a new observation, and may be valuable in the future in determining and better localizing the right centre. In this case there have been no epileptic attacks since operation. In the first case there were several attacks during the past summer.

Case 3 was one involving the removal of the centre for the left hand and wrist. The operation was followed by recovery.

The patients were presented.

SECOND DAY—MORNING SESSION.

DR. HUNTER MCGUIRE, of Richmond, Va., read a paper on

THE FORMATION OF AN ARTIFICIAL URETHRA FOR PROSTATIC OBSTRUCTION.

He said: It has been my lot to meet with a number of cases of hypertrophy of the prostate gland, which produces more or less obstruction to the passage of urine. These are conveniently divided into three classes:

1. Cases where the obstruction was due to temporary congestion of an already enlarged gland, which yielded to the ordinary treatment and did not return.

2. A class of cases where the obstruction to the passage of urine was permanent but not great. Attention to the general health, the occasional introduction of the catheter and washing out the bladder were all that the cases required. These cases are, however, never free from danger from exposure, etc., and gradual enlargement may go on and bring about the condition met with in the third class.

3. In these cases the obstruction is great and fixed, micturition is frequent and difficult, perhaps impossible without the aid of the catheter. The introduction of the instrument grows more and more difficult, offensive residual urine is always present, and the general health suffers greatly. Cystitis, localized or general, is a painful and pronounced symptom. Violent tenesmus of the bladder, provoked by the obstruction, injures the vesical ends of the ureters, possibly a reflux of stale urine is driven into these canals and ureteritis follows, then pyelitis and pyonephrosis, from which the patient dies.

The paper was devoted to a consideration of surgical interference in this third class of cases. He was led to resort to the measures described from the following circumstances: During the past eight months four cases of stone in the male required the suprapubic operation; two because of organic stricture; one because of the large size and hardness of the two calculi the bladder contained; the fourth because the stone was large and hard and the patient too anæmic to bear the shock and loss of blood which often accompanies section through the rectum.

In one of the cases of stricture, in a man 65 years of age, the patient had, two years before coming under observation, a second cause of obstruction. A well organized stricture was found in membranous portion of urethra. Prostate was enlarged, more marked on the left side. Urine showed no evidence of renal disease. An oxalate calculus $\frac{3}{4}$ inch in diameter was also recognized. The high operation for stone was performed. The bladder walls were found thick and unyielding, and contracted. The left side of the gland jutted into the bladder $1\frac{1}{2}$ inches further than the right side. The middle lobe was of the size of the thumb and almost completely closed the urethra. It was decided to retain a fistulous opening through which urination could take place. This tract was $2\frac{1}{2}$ inches long and extended upward and forward. In its passive state it was closed by the pressure of the parts through which it passed. When the bladder became full and contracted the urine was forced through the fistulous tract. He can now retain water for two or three hours, and has voluntary power both to retain and expel urine.

The second case was a man 69 years of age who had been cut for stone in 1881. In 1883 I found the prostate enlarged and cystitis present. He was given a gum catheter and shown how to use it. In 1886 electrolysis was employed without success in trying to reduce the size of the prostate. July 4, 1888, an operation similar to that performed in the first case was done, with equally good results. At times he is able to retain urine for six hours. He never has any desire to empty the bladder, no matter how full the organ is.

Mode of Operation.—The night before the operation the bowels are opened. On the day of operation 15 to 20 grs. of quinine are administered. Antiseptic precautions are adopted throughout. The bladder is washed out with a weak solution of carbolic acid in hot water. An empty gum bag capable of holding 12 ozs. is passed into the rectum. About 12 ozs. of water are then introduced into it. This pushes the bladder above the pubes. The bladder is next filled with a hot solution of carbolic acid. The use of force should be avoided. The penis is tied with a piece of rubber tube to prevent escape of the fluid. A vertical incision is next made, beginning 3 or 4 inches above the pubes and extending to the symphysis. This extends to the linea alba. The incision in the latter should be from $\frac{3}{4}$ to 1 inch shorter than that through the skin. When the transversalis fascia is reached it should be divided, but not for more than 2 inches, but should reach to the pubic bone. The fat and cellular tissue between the transversalis fascia and bladder is separated with the handle of the knife; this tissue should be disturbed no more than necessary. The bladder is now drawn forward with a tenaculum and opened as low down as possible. The interior of the or-

gan should be carefully explored with the finger.

Sutures should now be applied, extending down to but not including the recti muscles. The opening left in the skin should be at the upper extremity of the wound, so that the fistula will be oblique and from $2\frac{1}{2}$ to $3\frac{1}{2}$ inches in length. A catheter is passed through this opening. If the catheter causes annoyance it may be at once removed, otherwise it is better to allow it to remain a few hours. The dressing consists of a pledget of absorbent cotton changed as often as necessary. In none of my operations have I met with the peritoneum.

In the after-treatment it is important to keep the urine acid, for acid urine is aseptic. In operating on these cases and in the high operation for stone, the amount of blood lost has not exceeded 2 drachms.

DR. JOHN H. PACKARD, of Philadelphia, read a paper on

SUPRAPUBIC CYSTOTOMY.

The present paper was supplementary to one on the same subject read by Dr. Packard at the last meeting, and was intended to correct an accidental omission of the views of Sir Henry Thompson. These were now considered, extensive quotations from the works of this author being given. Two cases were reported, in one of which the operation was performed for the removal of a portion of silver catheter broken off in the bladder, and in the other for the removal of a piece of rubber catheter said to have been broken off several months previously. In this case a stone weighing 571 grs. was removed, in the interior of which was found the foreign body.

DR. S. W. GROSS, of Philadelphia, thought that Dr. McGuire was to be congratulated on having introduced a new operation based upon the mechanism of the bladder and the physiology of micturition—the formation of an artificial urethra in a new position. The various operations which had been performed for the relief of prostatic obstruction were next referred to. The operations of Harrison, Mercier, Bartimini and McGill were considered.

DR. WM. T. BRIGGS, of Nashville, thought that perhaps, in the cases reported by Dr. McGuire, a better result might have been obtained by the lateral lithotomy provided the stone were not too large to be removed by that route, for he had noted that after incision into the prostate the gland diminished in size, and after the wound had healed a catheter could be passed in cases in which its use was before impossible. The perineal operation allows of freer drainage. Under some circumstances the suprapubic operation is a valuable one. This is especially the case where the stone is so large that removal through the perineum is liable to produce serious injury of the soft parts. It is, however, often possible, through an incision in the perineum, to so break the stone as to per-

mit its removal. Every case should be studied by itself; in some one operation is the best, in others another is most suitable. All the circumstances of the case must be taken into consideration.

MR. REGINALD HARRISON, of Liverpool, said that there are two general methods of relieving obstruction due to enlarged prostate, one by attaching the gland through the bladder, and the other through the perineum. In his operation he makes a median or a lateral incision through the perineum according to circumstances. The obstructing prostate is next divided with considerable freedom and a drainage-tube of considerable size introduced. From this operation he gets good results. Perineal lithotomy is preferable to the suprapubic operation because the lateral incision gives sufficient room for all manipulations. It gives an ample opening for the removal of a stone of considerable dimensions. It also permits of the more or less permanent drainage which these cases require. He had also, through a perineal opening, used the perineal lithotrite with success. All methods of operation should be remembered and each employed in those cases where it seems indicated.

PROF. THOMAS ANNANDALE, of Edinburgh, had come to the conclusion that if an operation is to be performed for the relief of prostatic obstruction, the perineal operation is the best. This allows of examination of the bladder, permits drainage and probably causes a diminution of the hypertrophy. It enables you to occasionally remove a portion of the enlarged prostate when this assumes a pedunculated form. The speaker exhibited a rubber tube which he had found useful in cases of Harrison's operation, when a permanent tube is required.

DR. A. VAN DERVEER, of Albany, said that the testimony presented in his paper last year was in favor of the perineal opening so far as drainage was concerned. He had employed Harrison's operation in a number of cases and the results had been such as to impress him favorably.

MR. ARTHUR DURHAM, of London, emphatically endorsed what had been said in regard to operation of stone, that no one operation is applicable to all cases. It is a great mistake to be men of one method, especially in surgery. When we hear a man say that he treats all his cases of fracture in such a way, all his cases of stone in such a way, and all his cases of prostatic disease in such a way, he may be sure that such a man has a very small practice and experience, or else is deficient of proper discrimination. In cases in which stone in the bladder is complicated with enlarged prostate, the perineal incision seems to me to be better than the supra-pubic. He described a method of performing perineal lithotomy which is performed with satisfaction at Guy's Hospital. This consists in the use of a straight

staff, the groove extending to within one-third of an inch of its extremity. A knife with a straight back is passed through the perineum until it reaches the groove, then carried along the groove to its extremity and the point of the knife being held in close contact with the staff, the two are carried forward into the bladder, thus avoiding many of the risks of the operation as ordinarily performed. In concluding he referred to the great improvement of the Bigelow operation over the old method of crushing for stone. He had no doubt that this method render both lateral and supra-pubic lithotomy much more rare than they have been in the past.

PROF. HINGSTON, of Montreal, believed that the supra-pubic operation was one to be performed only in exceptional cases. These he classified as follows: 1. In those cases of stricture in which the obstruction cannot be overcome in time to relieve the patient of great suffering. 2. In cases of prostatic obtrusion. 3. In cases of tumors of the bladder which would interfere with the lateral operation. 4. In cases where the stone is too hard or too large to be removed either by lithotomy or by lateral lithotomy. He had himself removed without injury to the soft parts, a stone weighing five ounces and five drachms.

SIR WILLIAM MACCORMAC, of London, had performed the operation of supra-cystotomy occasionally. He had never seen any untoward consequences and the operation seems to be devoid of all risk. He did not consider that drainage was necessary after this operation. The bladder empties itself freely and the drainage tube is a source of irritation.

DR. H. MCGUIRE said that the only object of his paper was to describe the two cases in which he had made an artificial urethra to relieve prostatic obstruction. The various operations referred to were not applicable to all cases, while the formation of an artificial urethra could be done in all cases. He was surprised to hear that supra-pubic cystotomy was considered dangerous. It had the advantage of avoiding some of the unpleasant consequences of the lateral operation such as dribbling of urine and impotence.

DR. J. H. PACKARD did not want to be considered as an advocate of supra-pubic cystotomy. It had, however, been shown that the dangers attributed to this operation did not exist. He considered that the operation was a valuable resource in certain cases. After this operation he had noted diminution in the size of the enlarged prostate. This he attributed to the rest afforded the bladder. It will take place in whatever way the rest may be obtained.

THE PRESIDENT, DR. D. HAYES AGNEW, being called upon, said the ground had been so thoroughly covered that there was little to be added. He agreed with those who held that no single operation was applicable to all cases. The supra-

pubic operation may be appropriate in certain cases, while in others the perineal operation is the proper one. In order to avoid the unpleasant consequences which occasionally follow the perineal operation in children where the prostate is small, I avoid the introduction of the finger into the bladder and remove the stone with forceps not much larger than the staff.

While there may be no danger in the supra-pubic operation in skilled hands, yet with the inexperienced operator there will be risk of opening the peritoneal cavity. He thought that a number of cases had been reported of rupture of the bladder following injection of the organ after dilatation of the rectum with the rubber bag.

A paper entitled *Forty Years of Chloroform and Ether, in Louisville, Ky.*, by DR. D. W. VANDELL, of Louisville, Ky., was read by title.

The following are the

OFFICERS OF THE ASSOCIATION FOR THE ENSUING YEAR:

President—Dr. D. W. Cheever, of Boston.

Vice-Presidents—Dr. T. W. Richardson, of New Orleans, and Dr. John B. Roberts, of Philadelphia.

Secretary—Dr. J. R. Weist, of Richmond, Ind.

Treasurer—Dr. P. S. Conner, of Cincinnati.

Recorder—Dr. J. Ewing Mears, of Philadelphia.

Additional Members of Council—Dr. W. F. Peck, of Davenport, and Dr. S. W. Gross, of Philadelphia.

The next meeting to be held in Washington, beginning the second Tuesday of May, 1889. Chairman of Committee of Arrangements, Dr. J. S. Billings. Member of Committee of Arrangements, Dr. J. Ford Thompson, of Washington.

THURSDAY, THIRD DAY.

DR. GEO. W. GAY, of Boston, read a paper on

THE COMPARATIVE MERITS OF TRACHEOTOMY AND INTUBATION IN THE TREATMENT OF CROUP.

As to results, the conclusion was reached that the new operation saves nearly or quite as many patients as did the old.

In regard to the facility of doing intubation, it may, like tracheotomy, be easy or difficult, according to the age of the child, the condition of the larynx and the strength of the patient. Both operations are difficult in children under three or four years of age, and both are attended with some danger. In tracheotomy the risk lies principally in hæmorrhage and collapse. In intubation it lies in pushing membrane, etc., down in front of the tube, producing more or less complete obstruction. In very weak children collapse may result from prolonged efforts at placing the laryngeal tube. Under these circumstances the sur-

geon should choose the operation with which he is most familiar. The old operation can be done with one good assistant. Intubation requires at least two fairly good ones. Unless great care be taken the operator's fingers may be severely bitten, which, in at least one case, has resulted in death.

It is desirable to have a physician close at hand for three or four days after both operations. If the tube must be allowed to take care of itself, intubation is preferable. If ordinary care, such as a good nurse or other clever person can give, is available in cases located at a great distance from a physician who can place O'Dwyer's tubes, then the old operation is better, there being less danger of fatal obstruction, and the question of feeding giving less anxiety.

The weight of testimony goes to prove that it is less work to take care of intubated than of tracheotomized patients. The time occupied in caring for the tube in the latter class, is largely taken up in feeding the former class of patients.

Northrup's statistics of 107 autopsies performed at the New York Foundling Hospital, go to prove that there is no such thing as "food pneumonia," as in no instance were signs of food found in the smaller bronchi. Dr. O'Dwyer advances the opinion that the secondary lung affections, especially of pneumonia, are due to retained secretions which, owing to the pressure of the tube in either operation, can not be ejected in coughing. Others think that this complication is due to the fact that the air enters the lungs without first being warmed and moistened by passing through the nasal chambers. The author ascribes these affections to the natural tendency of exudative processes to extend in all directions, and bases the opinion upon the fact that pulmonary complications are as frequent in cases not receiving surgical treatment, run the same course and are as fatal as in those in which operation is resorted to.

While a wound in the skin is objectionable on general principles, yet the wound of tracheotomy gives little trouble and does little harm. The diphtheritic poison gains admission to the system before the wound exists, and the course of the disease as regards sepsis is the same after as before the operation. In only six of the 327 operations at the City Hospital of Boston was diphtheria in the wound noted; three of these cases recovered. Both tubes may produce ulceration in the trachea, but the result is seldom serious.

Conclusions.—1. Intubation may be tried in all cases of croup.

2. It is preferable in young children and in cases in which the tube must be left entirely to itself.

3. It may be resorted to for euthenasia, provided the operator is reasonably expert and can do it without producing collapse.

4. Tracheotomy is called for in those cases in

which intubation can not be done or in which it fails to give relief; or in which the laryngeal tube is repeatedly rejected, or requires frequent removal for cleansing. It may also be required in those cases in which sufficient food can not be given while the O'Dwyer tube is in position. It is also preferable in cases situated at a distance from a surgeon capable of introducing the laryngeal tube.

5. The tracheotomy instruments should always be at hand in intubation in case of emergency.

DR. H. H. MUDD, of St. Louis, said that intubation had been done as a precautionary measure in many cases in which tracheotomy would not have been thought of. Some of the good results of intubation are to be attributed to this fact. In most of his cases of intubation, where the patient survived he had found it necessary to resort to tracheotomy; patients had recovered after tracheotomy where intubation has proved unsuccessful.

PROF. THOS. ANNANDALE called attention to the value of the introduction of a tube through the glottis in case of operations about the throat where there was risk of suffocation or of hæmorrhage into the trachea.

DR. HUBER, of New York, had performed intubation in 94 cases with recovery in 37. He does not operate early. He considers the internal use of bichloride of mercury as of equal importance as the intubation. There is occasionally an advantage in using a small tube with the expectation that it will be coughed out, and with it a portion of the membrane, and affording an opportunity for feeding while the tube is out.

DR. T. F. PREWITT, of St. Louis, in one case of diphtheritic paralysis had, in order to avoid passage of fluid into larynx, passed a catheter through the glottis and plugged the larynx with a sponge. This permitted the fluid to go into the œsophagus without risk of entering the trachea. After feeding, the sponge and tube were removed.

DR. D. W. CHEEVER, of Boston, advocated the disuse of anaesthetics in cases of tracheotomy provided proper assistants can be secured. The operation is not accompanied with much pain. By avoiding the anaesthetic many of the risks of the operation are avoided.

DR. D'FOREST WILLARD, of Philadelphia, read a paper on

NEPHRECTOMY. 1. GUN-SHOT WOUND OF THE KIDNEY. 2. TUBERCULAR DISEASE OF THE KIDNEY.

Abdominal section was performed in the first case, but the patient died of loss of blood eighty-six hours after the injury.

In his remarks on this case Dr. Willard dwelt upon the advantages of abdominal incision, where the probabilities of other organs having been injured were so great; as hæmorrhage could be

averted, perforations repaired and escaped fluid removed. Drainage through the loin or abdomen was not advisable, provided urine had not escaped into the peritoneal cavity before the operation. The hæmatocele, if large and retroperitoneal, could not be thoroughly removed, and should therefore be allowed to remain undistended. All fluids in the abdominal cavity should be removed.

The three primary nephrectomies for gunshot wound thus far reported have all been done by Philadelphia surgeons. Keen (*Transactions American Surgical Association*, vol. v, p. 193), removed the left kidney of a girl of 18, in whom the ball had perforated the stomach, liver, spleen and kidney. This patient died on the fifteenth day. Price (*Trans. Penn. State Society*, 1888), removed the right kidney in a girl of 14, in whom the liver was also perforated. His patient recovered after multiple abscess of the liver. Dr. Willard's case died on the fourth day. In none of these cases was there anuria.

Case 2. Nephrectomy for Tubercular Kidney.—Female, æt. 32, married eight years but never pregnant. Tubercular history of ancestry uncertain. Failing in health for ten months; seven weeks ago first noticed tumor in right side of abdomen, has had increasing pain in this region, this is now very severe at times. Has emaciated rapidly. Temperature varying from 99° in the morning to 101° in the evening. Diarrhœa quite constant; passes large amounts of pus in the urine, urine $\frac{1}{6}$ albuminous, but contains no casts and no distinctive cell elements. Tumor, rounded in form, occupies the space from the right renal region forward to linea semilunaris, and vertically from lower margin of liver to line of anterior superior spinous process. Indistinct dullness extending into pelvis; resonance between liver and tumor, tumor movable.

Diagnosis uncertain as to purulent kidney or sarcoma of kidney. The size of the tumor and its projection forward determined the selection of the abdominal median incision. The right side of abdomen was found filled with thick sac, giving indistinct sense of fluctuation. From it extended downward two elongated masses, one evidently a pus-filled ureter, and the other a mass extending down from the external iliac vessels and passing under Poupart's ligament. Puncture evacuated only a few drachms of pus and did not diminish its size. Tearing open the sac, the kidney was found riddled with multiple abscesses. The vessels and the ureter low down were tied with silk ligatures and the kidney removed. The abdominal cavity was irrigated with distilled water, drainage-tubes inserted behind the uterus and into the site of the nephrectomy, and the wound closed with one set of sutures. The woman was exceedingly low during the operation, but rallied so that the temperature rose to 99° and she became perfectly conscious. Two hours after operation she suddenly sank and died.

Post-mortem examination showed that behind the suppurating kidney and in a separate sac, divided from it by a wall 3 lines in thickness, was another pus sac. This sac was 3 inches wide, and the pus had worked its way down the aorta, common iliac and iliac arteries to Poupart's ligament. If nephrectomy had been attempted this sac might have been drained and the kidney never reached at all. No hæmorrhage after operation. Death from shock. The other kidney was enlarged but not diseased.

DR. W. W. KEEN believed that blood exuded between the folds of the peritoneum was not a source of danger and that it might be left without interference. If we could make out that the kidney alone was injured the lumbar incision would be the proper one. Where there is a probability of injury of other structures the abdominal incision is the best.

DR. L. McLANE TIFFANY, of Baltimore, held that in simple gunshot wound of the kidney the proper plan was to drain the kidney through the lumbar region and not to perform nephrectomy.

DR. CHAS. T. PARKES, of Chicago, reported a case of gunshot injury of the abdomen, in which in addition to a number of perforations in the bowel the ball entered the kidney. The intestinal wounds were closed. No operative procedure was performed on the kidney. The patient died from hæmorrhage of the kidney twenty-four hours later.

DR. KEEN thought that in the condition referred to by Dr. Tiffany the proper plan was to drain, but where there is much injury of other parts the patient will stand a better chance if the wounded kidney is removed.

DR. ROBERT F. WEIR, New York: If there is simply a gunshot wound of the kidney, the organ should be thoroughly exposed in order to ascertain the extent of the injury. Then thorough drainage should be employed, and to guard against hæmorrhage the wound should be tamponed with iodoform gauze.

Obstetrical Society of Philadelphia.

Stated Meeting Thursday, September 6, 1888.

J. C. DACOSTA, M.D., IN THE CHAIR.

(Continued from p. 462.)

DR. H. A. KELLY reported

A CASE OF CÆSAREAN SECTION.

He operated April 17, of this year, delivering a living child and saving the life of the mother.

The patient a slight woman, 4 ft. 4 in. in height, had been in labor two weeks, her physician, Dr. Ireland, having watched by her bedside constantly for nine days previous to the operation. The waters ruptured four days before operation.

The estimated actual conjugate diameter was two and a quarter inches, although the pelvis was so choked by general cedema and hard cellulitis masses that it was impossible to recognize any structures with satisfaction, much less reach the presenting part of the child.

The patient's pulse at the time of operation was 142. The operation lasted thirty-five minutes. The after condition and convalescence was one of comfort and rapid recovery.

This makes the ninth case being operated on in Philadelphia, the first being by Professor Gibson in 1835, the historic case of Mrs. Reybold.

Dr. Kelly stated that he had since that time also operated upon another case for a relative indication, in preference to performing craniotomy upon a living child with the result of saving both mother and child; this question, however, of the relative indication was one of such importance, deserving such careful consideration, that he would reserve it for a more elaborately prepared paper at a future date.

DR. JOSEPH PRICE read a paper on

THE ABUSE OF CÆSAREAN SECTION.

On the legitimacy of the Cæsarean section, there cannot be now, under certain restrictions and limitations, a question. In extreme cases where hasty operation is necessary in order to save the life of the mother, where there is impaction or where there is a tumor blocking up the uterine or vaginal outlet, discussion or hesitation has little place, and he can operate best who has all resources at command and acts without hesitation.

The real points for discussion in the light necessity of the Cæsarean section, in order to terminate a labor, with greatest safety, first to the mother, then the child, are: first, "*The degree of contraction in the pelvis*;" second, "*The advancement of pregnancy*;" third, "*The chances for the induction of premature labor*." As to the first: As an epitome of the latest generally received opinion, we have the statement of Greig Smith: "The operation of Cæsarean section is said to be justifiable when the contraction is so great that we cannot expect to deliver the fetus per naturales vias, with or without embryotomy, and save the mother. The degree of contraction is generally stated as one and one-half inches and below. But in cases in which much distortion exists, may have an upward limit of two inches."

Here then is a plain expression of conservative opinion as to the degree of deformity necessitating or justifying the operation, "As to the induction of premature labor," says Playfair, "there are few practitioners who would not deem it their duty to spare the mother the dangers of the Cæsarean section," this being especially true since "there is no amount of deformity, however great, in which we could not succeed in bringing

on miscarriage by some of the numerous means at our disposal."

The time at which premature labor should be brought on varies, of course, with the degree of deformity of the pelvis; the tables of direction have been admirably constructed by Kiwisch. Briefly, the period for induction of labor lies between the 30th and 36th weeks, and the corresponding sacro-pubic diameters vary between 2 inches and 6 lines and 3 inches and 5 or 6 lines. Here, then, naturally follows a discussion of the means for inducing premature labor. Of the many methods proposed at different times, the one seemingly the best is the soft catheter. Its introduction well into the uterus, for a distance of six or seven inches, is an almost certain means of speedily producing labor pains safely.

I consider the British rule, that Cæsarean section should never be an operation of selection, but one of necessity, in general terms, as the safeguard of puerperal women. Once establish the precedent that Cæsarean section is an elective procedure in obstetrics, and thereby lay down also the principle that abdomino-uterine section is a safer procedure than the introduction of a soft catheter into the uterus before full term, the way is laid open to every aspirant for obstetric fame, who is the fortunate possessor of a knife, to find cases for his zeal at every court and corner in the city, if perchance he can, of himself, persuade the parturient woman of the necessity of delivery by "*the new natural method of delivery*."

An axiom as to the operation is laid down by Lusk: "The precise limits at which the dangers of delivery through the pelvis rise to the level or exceed those from Cæsarean section, is not easy to determine. It depends partly upon the size and ossification of the child's head, and largely upon the experience and dexterity of the operator." The converse of this proposition is true also. The greater the experience and the more careful the observation of the operator, the less frequently will he be led to resort to Cæsarean section, if he hold in mind that it is an operation of necessity, not of election.

Two cases will illustrate the dangers here referred to, and the justness of these forebodings.

Case 1.—A woman already delivered of a living child, yet living at four years. Three other deliveries at term with the forceps. All of these children dead. No attempt at premature labor. In the fifth pregnancy she is decided upon as a case for Cæsarean section. She passes into the hands of another attendant, who, after careful pelvic measurements with a consultant, decides on premature labor. The woman delivers herself, without instruments, of a child whose head has a biparietal diameter of $3\frac{1}{4}$ inches, the period of gestation being $8\frac{1}{2}$ months. The previous measurements of the pelvis having decided upon an antero-posterior diameter of $3\frac{1}{2}$ inches.

Case 2 is an actual operation. A woman in third pregnancy. First child delivered after 30 hours' labor, with instruments, dying soon after birth. Second pregnancy, she delivered herself of a child of normal proportions, at full term, without instruments. The child yet living. Third pregnancy, Cæsarean section. Recovery after protracted convalescence; child still living. Here are lessons full of instruction. What do they teach?

DR. M. PRICE thought that the duration of labor had nothing to do with the choice of Cæsarean section. He had delivered a woman two weeks since, who had been in labor seven days. It was an occipito-posterior position, and the cervix did not dilate more than enough to permit the introduction of two fingers. He introduced his hand, dilated the os, and applied Simpson's forceps. The delivery occupied an hour and a half, but the woman made a good recovery. Had the case been delayed a few days longer there might have been a necessity for Cæsarean section. Where there is an inflammatory or cedematous condition of the pelvis, he thought there should be some forcible measure adopted for the delivery of the patient.

DR. W. M. GOODELL thought that the title of Dr. Price's paper was not a fortunate one, for the gentlemen who are called upon to perform Cæsarean section are usually not the attending physicians, and they have had nothing to do with the previous medical attendance on the patient. He believed in the induction of premature labor, and would do it in preference to the performance of Cæsarean section. But often the patient herself will not submit to the induction of labor. Dr. Price would probably admit, one day, into the "Retreat," an Irish woman who has had the most frightful labor, and who had persistently refused, from conscientious motives, to permit the induction of labor. He could conceive of cases where it would be better to perform Cæsarean section, although he had never as yet done so. Probably in some of the cases in which he had formerly opened the head, he would now do Cæsarean section. He thought a woman might go on safely in labor for an indefinite time, so long as the bag of waters had not ruptured, with very little danger to herself.

DR. H. A. KELLY remarked that the bag of waters had ruptured four days before the operation. The pains had been very hard before this time, and did not change in character afterwards, although the woman soon dropped into collapse. The pelvis was so choked by hard cellutic mass that it would have been impossible to dilate anything or reach anything above the mass. The second paper evidently referred to his case performed on a relative indication, in preference to craniotomy. That case he had not yet reported, reserving it for a full careful discussion. Where

any such garbled, distorted particulars had been hunted out he did not know, nor could he reply to criticisms offered in such a tone. His profession was his life, and he came here to impart and still more to receive information in a spirit becoming the dignity of the profession, and he would not make life unhappy by taking part in any miserable bickering.

DR. J. PRICE said that in a long experience in the Obstetrical Department of the Philadelphia Dispensary he had numerous cases of deformed pelves and illy-developed women, some of them very young. He would simply call attention to two typical cases.

Case 1.—A case in which Dr. Eliot Richardson had five times done craniotomy or complete evisceration. This woman applied in her sixth pregnancy to the Philadelphia Dispensary and was assigned to Dr. Joseph Fox for induced labor—in a period of five years he had induced labor three times in this case, delivering by forceps and saving two children—one still-born.

Case 2.—Also a Dispensary case. Had in her five previous labors had the children destroyed. The sixth was provoked at eight months and two weeks, and she was delivered with forceps of a fine, large male child.

In a short experience at the Preston Retreat he had dealt with two cases of greatly contracted pelves, in both of which Dr. Goodell had twice or thrice induced labor, delivering living children. Recently two cases were sent in for induced labor or Cæsarean section. The consultants determined on the induction of labor. Both cases terminated favorably, with living children—one of them was a forceps delivery, the other normal. These are only typical cases, but few of the many he could cite in his own experience. If Dr. Kelly was satisfied that the last case given in the paper was his second Cæsarean section, he was sure he was welcome to his knowledge, as no one would wish to lay claim to it.

DR. J. PRICE exhibited a specimen of a small male foetus, at about the third month, removed from a case of extra-uterine pregnancy. Patient healthy and twice married. There had been numerous attacks of pain. Recovery from operation was rapid. The following week he did an abdominal section on a woman who was unconscious and removed an extra-uterine pregnancy. She died twenty-six hours later. This was the sixth case of extra-uterine pregnancy which had developed in his practice in four weeks. One case he went into the country to operate and found the patient dead when he arrived. Dr. Formad told him that this was a very common result in his experience as coroner's physician.

He also showed a dermoid cyst, removed from a woman who has suffered from chronic peritonitis for years. Her physician had given her as much as a grain of morphia hypodermically, and had

sat up all night etherizing her to relieve her pain. She was greatly emaciated, with a rapid, feeble pulse, high temperature, and had been in bed for six weeks. Whole tumor enucleated, no ligatures required. Intestines separated and irrigated—glass drainage. This is the 9th day and she is rapidly convalescing.

FOREIGN CORRESPONDENCE.

LETTER FROM LONDON.

(FROM OUR OWN CORRESPONDENT.)

The Cancer Hospital—Economy of Sanitation—Enemas of Antipyrin to render Labors Painless—Saccharin as a Preventive of Ammoniacal Urine in Cystitis—Glycerine in Suppositories—Fatal Results of Erroneous Vaccination of Sheep from Anthrax in Russia—New Antiseptic Soap.

With a view of affording a few hours diversion and entertainment to the poor sufferers of the institution, a garden party has just been held in the spacious grounds of the well known Cancer Hospital in the Fulham Road. The band of the A Division Metropolitan Police was in attendance. Out of the seventy patients at present in the hospital nearly fifty were sufficiently convalescent to leave their wards and partake of the refreshments provided for them in the grounds. The hospital which is free, was founded by Dr. Marsden in 1851, and since then has given relief to 27,131 persons afflicted with cancerous disease. It has recently undergone great extension, and is now complete and capable of receiving upwards of 100 indoor patients. During the last year the total number of new patients was 1,715.

At the annual conference of public sanitary inspectors of Great Britain held at Brighton, Dr. B. W. Richardson contended that the advance of sanitation, notwithstanding the heavy expense entailed, had brought about a general improvement in public health, as shown by the death-rates, and at the same time had been brought about by the application of the true spirit of economy. The cost of prevention was one-third the cost of disease. In many ways sanitary efforts had been impeded by over-crowding, and it was incumbent upon the public authorities to secure increased space in order to alleviate the evil. Improved school premises had done its work in reducing children's diseases, and the same causes had followed improved barrack accommodation in the army.

A German practitioner has lately stated he has succeeded in minimizing, or even preventing entirely, the pains of childbirth, by the administration of enemata of antipyrin. In the case of one woman, with her first child, who had been in great agony for upwards of twenty hours, a single

injection per anus of about half a drachm of antipyrin to a few ounces of water, the pain ceased almost immediately as if by magic, although the uterine contractions continued without alteration or diminution, and the accouchement proceeded in an entirely satisfactory manner. He also records cases where one or two antipyrin enemata rendered premature labor absolutely painless. Another authority, Dr. Layel, of Marseilles, has met with the like success, in similar cases, by the employment of this drug. Equally satisfactory results have attended the administration of antipyrin in this manner in England, and consequently it is likely to be extensively employed. If it is really the fact that in addition to its other valuable properties, antipyrin is capable of doing away with the whole, or the worst of the horrible pains of parturition, an immense impetus will be given to the demand for this already very popular medicament. Thirty to thirty-five grains (two grams) is the quantity recommended for each enema, and even in very severe cases a second or a third injection, after a short interval, suffice to relieve the patient from all her pain.

Dr. James Little, in a paper upon "the value of saccharin in preventing the decomposition of the urine in cases of chronic cystitis, states that from his results it would appear, that although saccharin exerts no very marked effect in tubercular cystitis, or in other varieties of the disease not accompanied by alkaline urine, it had been employed with very beneficial effect whenever a highly ammoniacal state of the renal excretion was present. Saccharin in fact, appeared to act by neutralizing or diminishing the amount of free ammonia in the urine, whether this arose from stricture, paralysis or prostatic disease. The ammonia being kept down or extinguished by the drug, the affection then succumbed under the ordinary treatment. Dr. Little also bears testimony to the good effects produced by full doses of caffeine, combined with salicylate of sodium, in neuralgic and migrainous headaches.

The recent discovery that the injection of a minute quantity of perfectly pure glycerine would induce an action of the bowels, has given rise to the making of a new kind of suppository by a well-known firm. The suppositories are hollow cones made to contain exactly 15 grains of pure glycerine. One is said to produce the desired action of the rectum.

The death of 5,000 sheep in Russia through being under the vaccinal treatment of Dr. Gamaleia for anthrax, seems to have been due to an incomprehensibly stupid error on the part of an assistant. For anthrax the sheep are twice inoculated, the first lymph being mild and the second and last intensive. In each case the vaccine matter consists of one-eighth of a cubic centimetre. The first produces in the sheep a vaccinal fever of one or two degrees, insufficient to

kill a guinea pig or rabbit, but fatal to mice and other small rodents. The second and more intensive injection produces also a temporary vaccinal fever after which the sheep is impervious to plague. But this second vaccine administration without the first gives a fatal result in nearly all cases. The fatal result was the natural consequence of the vaccinator—an assistant, administering the second vaccine in the first place. Usually an interim of from ten to fourteen days is allowed between the two vaccinations.

Probably no living member of the Russian faculty, old or young, has accomplished within so short a career so much hard and tedious labor as Dr. N. F. Gamaleia. He first became a disciple of M. Pasteur in the early part of 1866, since when he has worked with an enthusiastic and unremitting energy in the pursuit of tangible results in germinal diseases, at the same time personally conducting the daily inoculatory courses for hydrophobia among the large numbers of patients from all parts of Russia, Turkey and Southeastern Europe. After matriculating at the Odessa University, he proceeded to St. Petersburg, where he received his doctor's degree. His vacations he spends in Strasburg, Vienna and Paris. After some further experimental operations during the present month, Dr. Gamaleia will go to Paris and London, probably about the end of October or early in November, when, in conjunction with M. Pasteur, convincing proofs will be given of the splendid successes obtained by his laborious researches.

The Duchess of Connaught has attended a St. John's ambulance for ladies in Poona, India, and has been awarded a certificate after, it is stated, passing a very satisfactory examination.

A new antiseptic soap is coming into use in some of the London hospitals, containing from 1 to 3 per cent. of biniodide of mercury (rendered permanently soluble by the presence of a little iodide of potassium). It is found to be a more powerful antiseptic microbicide than any hitherto known.

DOMESTIC CORRESPONDENCE.

A Case of Furuncle with a Singular History.

Dear Sir:—Clark, æt. about 27 years, came to my office June 28, 1888, accompanied by his wife. After prescribing for Mrs. C., the husband called my attention to a small tumor located on the upper lip near the line of the nose, about the size of a two-cent piece, which he stated had made its appearance a few nights previous.

From its sudden development, its rapid growth, its size and color, it was evident to my mind that it was nothing more than a small blind boil, and

I therefore prescribed for him accordingly. In the course of three weeks he again made his appearance, with his upper lip disfigured by several scars, marking the location where the boil had been. He stated that, a short time after leaving my office, a physician led him to believe that the small growth was a cancer, and required immediate removal.

The report of the operation was published in a local newspaper of this town, and reads as follows: "About five weeks ago a physician brought a patient to Dr. Woodward for the removal of an epithelial cancer situated on the upper lip and quite extensive in its development. Dr. Woodward decided that the best method of removal was by electricity. In the presence of two other physicians he performed the operation successfully and without drawing a drop of blood. The operation occupied only fifteen minutes. In ten days the wound was entirely healed and the cure perfect. The patient is now perfectly well."

J. F. JENKINS, M.D.

Tecumseh, Mich., September 21, 1888.

NECROLOGY.

Mary France Thomas, M.D.

Mary France Thomas, M.D., died at her home in Richmond, Ind., of dysentery on the 19th of August, 1888, aged 72 years. Her maiden name was Myers, and she was born in Bucks County, Pa., September, 1816. While still an infant her parents moved to Washington, D. C., and in 1833 thence to New Lisbon, Ohio, where she remained until her marriage. In 1853-4 she attended medical lectures in Philadelphia, in 1854-5 in Cleveland, and in 1869-70 in Indianapolis. In 1856, she with her husband and family removed to Richmond, Ind., which has since been her home and the field of her labors.

During the war she rendered special hospital service in Washington, Nashville and elsewhere, by appointment of Gov. Morton, and for about a year she was similarly engaged in Nashville under the direction of the Christian Association. For twelve consecutive years she was physician to the Richmond Home for the Friendless, and for about eight years she gave professional attention to the poor in one district of the City and suburbs by appointment of the authorities. In 1839 she married Dr. Owen Thomas, and in November, 1848, their third and last child was born, the husband at the time being in delicate health. When this child was 3 months old she resolved to study medicine as the most available means of supporting herself, her children, and her invalid husband. Her husband was her preceptor, and without neglecting any household duty or ma-

ternal obligation she prepared herself for college, and attended lectures as recited above. To accomplish this she overcame discouragements and surmounted difficulties that would have been impossible to a less self-reliant person; sustained by a conviction that her purpose was right and her labors in the line of duty, and the inspiration of the young mother found its justification and had its reward in thirty-two years of successful professional life, the fruits of which enabled her to properly educate her children and see them honorably settled in life, and until the end sustain her invalid husband who survives. She was a working member of Wayne County Medical Society and its president in 1887; presented a number of papers to the Indiana State Medical Society from year to year; and was a member of the American Medical Association.

Beside her active life as a physician, Dr. Thomas was a member of the Woman's Christian Temperance Union; of the Order of Good Templars; of the Prohibition Club; of the Woman's Suffrage Association; of the Board of Directors of the Home for the Friendless; and of the M. E. Church, and in each and every position was thoroughly imbued with the spirit, and engaged in the labor of the situation. In every organization of which she was a member she became president and an active manager of its concerns, and beside did yeoman's service in its ranks. One can but marvel how a woman not naturally robust could do so much mental and physical work.

Possibly there may be a margin for doubt, whether or not all the conclusions Dr. Thomas reached embodied the best practical methods for the betterment of the world in the line of her labors, but to those who knew her well there remained no shadow of doubt that she, in her own way, sought diligently for the true, and when she deemed it attained wrought with zealous assiduity to make it fruitful, but under all circumstances "with charity for all and malice toward none." It was significant of the dominant traits of her character continuing to the recognized limits of life, that in making arrangements in view of her rapidly approaching demise, she named six women to act as her pall-bearers, selecting two of her co-workers in the temperance field, two of her associates in the management of Home, and two colored to make her persistent sentiments of delight at the freedom, and her desire for the culture of the race.

J. F. H.

E. Williams, M.D.

Concerning the death of this distinguished member of the profession we copy the following from a recent Cincinnati paper. We are promised a proper biographical sketch of the deceased for our columns soon.

At a meeting of the medical profession held last evening at the Miami Medical College in response to a special call to take action on the death of Dr. Williams, Dr. John A. Murphy was chosen Chairman and as Secretary Dr. Robert Sattler, who has long been associated with the deceased. The following resolutions were adopted:

The death of Dr. E. Williams, the veteran and distinguished oculist of Cincinnati, deprives the ranks of the medical profession of one of its most useful men, and the community loses also a noble and unselfish friend of humanity.

As a man, he endeared himself by his cheery and genial disposition and his unselfish characteristics to his professional colleagues, both old and young, and no one more generously received the appreciation and gratitude of his patients.

As a physician, he was equally esteemed by the profession and the community for his untiring and energetic efforts to promote the advance of medical knowledge, and, in particular, of the department of ophthalmology.

Faithfully and zealously were his best endeavors and most assiduous energy devoted to this important division of the medical sciences. For a period exceeding thirty years he was active as a specialist, and devoted all his attention and time to ophthalmology and otology. Justly does he deserve the credit and distinction of having been foremost among a limited number of men in aiding toward the introduction and establishment of ophthalmology as a recognized department of medicine and surgery in America.

Throughout this long period he has been constantly identified with medical education. His superior qualifications as a medical lecturer and teacher gave him unlimited scope of usefulness as a successful instructor, and gratefully will he be remembered by a countless number of students.

His unlimited capacity for practical work afforded him opportunities to aid in the alleviation of suffering, and, with unremitting attention, he assumed and discharged faithfully the arduous duties of a college, hospital and dispensary position. He was lavish—it may be even said reckless—in his offering to charity and poverty-stricken patients, but if he erred in giving his services gratuitously, it was only to carry out his desire to do good for the sake of good, reward or no reward.

The medical profession of Cincinnati herewith acknowledge their appreciation of Dr. E. Williams as a distinguished physician, and unite in their expression of sorrow and sympathy over the announcement of his death.

JOHN A. MURPHY,

W. W. SEELEV,

S. C. AYRES,

W. H. TAYLOR,

ROBERT SATTLER.

The faculty of Miami Medical College met last evening and adopted similar resolutions.

MISCELLANEOUS.

THE PEOPLE'S FOOD QUESTION IN SWITZERLAND.—The Swiss Society for the Promotion of the Public Good has addressed to all the Working Men's Clubs, Mutual Coöperation Unions, and Agricultural Laborers' Associations throughout the Confederacy, a circular inviting their support in the work of improving and cheapening the alimentation of the people. An important advance in this direction might, the Society urges, be made by the extension of the use of milk and cheese as articles of consumption. Strange as it may appear, such food—so satisfying, so sustaining, and, if properly produced, so accessible to the very humblest—has yet to be made the subject of special recommendation to the comparatively well educated, undoubtedly intelligent, and industrious Swiss. Yet such is the case; and accordingly we read of an appeal to all branches of the above Society "to arouse in the popular mind an interest in the matter, as well as to open up the ways and means of extending the consumption of milk and cheese." For the furtherance of this object, proceeds the circular, "the local branches are requested to establish courses of culinary and household instruction (*Koch und Haushaltungskurse*), with immediate reference to the wants and circumstances of the laboring classes. For the conducting of such courses the pupils of the culinary school at Reussport, near Lucerne, are qualified and licensed. As has been done in the Canton Aargau, these branches can, in all the cantonal villages, establish dépôts for the supply of genuine milk and unadulterated cheese, and, in cases where during the winter they furnish the poorer children living at a distance from the school with the midday meal, they can make the said meal consist mainly of milk and cheese with bread." The agricultural branches of the Society are reminded that they are in a position to exert a salutary influence on cheese-production, and especially to diffuse the making of its household varieties, which has recently been brought so near perfection. To the artisan branches, on the other hand, appeal is made to promote the consumption of cheese by rendering it as accessible as possible, and moreover, in the interests of their respective *clients*, to see to the purity of the milk concurrently supplied. This Swiss movement is one to which sanitarians nearer home might well give attention, and its results should be watched and noted by all who realize the daily increasing urgency of the popular food supply in all countries.—*The Lancet*, September 22, 1888.

HEALTH IN MICHIGAN FOR SEPTEMBER, 1888.—For the month of September, 1888, compared with the preceding month, the reports indicate that remittent fever, bronchitis and influenza increased, and that neuralgia, cholera morbus, cholera infantum, consumption of lungs and erysipelas decreased in prevalence.

Compared with the preceding month the temperature in the month of September, 1888, was much lower, the absolute humidity and the day and night ozone were less, and the relative humidity was slightly more.

Compared with the average for the month of August in the nine years, 1879–1887, intermittent fever, typho-malarial fever, consumption of lungs, tonsillitis, whooping-cough, diphtheria, neuralgia and cholera infantum was less prevalent in September, 1888.

For the month of September, 1888, compared with the average of corresponding months in the nine years 1879–1887, the temperature was lower, the absolute and relative humidity and the day ozone were less, and the night ozone was much less.

Including reports by regular observers and others, diphtheria was reported present at twenty places in Michigan in September, 1888, scarlet fever at twenty-four places, typhoid fever at thirty-five places, and measles at seven places.

Reports from all sources show diphtheria at seven places less, scarlet fever at one place less, typhoid fever at seven places more, and measles at the same number of places in the month of September, 1888, than in the preceding month.

FOUR CHILDREN AT A BIRTH.—DR. PARK P. BRENE-MAN reports, in the *Australasian Medical Gazette*, of August, the case of a woman in Sydney, N. S. W., who gave birth last April to four children at one birth. The children, with the exception of the fourth, were expelled head first; the fourth was born feet first. The labor was very short, there being but thirty minutes from the time the first child was born to the completion of the labor; ten minutes between each child. The children were all born alive, and lived from two to six hours and a half. They were as large as the average 5½ months' child, perfectly formed, and well nourished.

ADULTERATED MILK.—A dairyman near Melbourne was recently fined \$25 and \$15 costs for having sold milk containing from 9 to 12 per cent. of added water, and deficient in butter fat 23 per cent.

DR. WILHELM BIEDERMANN, of Prague, has accepted the chair of Physiology in Jena, vacated by the resignation of Professor Preyer.

THE INTERCOLONIAL MEDICAL CONGRESS of Australasia will be held in Melbourne in January, 1889.

Official List of Changes in the Stations and Duties of Officers Serving in the Medical Department U. S. Army, from September 29, 1888, to October 5, 1888.

Major Henry M. Cronkhite, Surgeon, on being relieved by Capt. Corbusier, will report for duty to the commanding officer, Little Rock Bks., Ark., reporting by letter to the commanding General Div. of the Atlantic. Par. 10, S. O. 227, A. G. O., Washington, September 29, 1888.

Capt. George W. Adair, Asst. Surgeon, is relieved from duty at Ft. Brady, Mich., and will report for duty to the commanding officer, Ft. Robinson, Neb., reporting by letter to the commanding General Dept. of the Platte. Par. 10, S. O. 227, A. G. O., Washington, September 29, 1888.

Capt. William H. Corbusier, Asst. Surgeon, on being relieved by Capt. Taylor, will report in person to the commanding officer, Ft. Hays, Kan., for duty at that post, relieving Major Henry M. Cronkhite, Surgeon, and reporting by letter to the commanding General Dept. of Ariz. Par. 10, S. O. 227, A. G. O., Washington, September 29, 1888.

Capt. Arthur W. Taylor, Asst. Surgeon, is relieved from duty at Ft. Robinson, Neb., and will report in person, without delay, to the commanding officer, Ft. Grant, Ariz. Ter., for duty at that post, relieving Capt. William H. Corbusier, Asst. Surgeon, and reporting by letter to the commanding General Dept. of Ariz. Par. 10, S. O. 227, A. G. O., Washington, September 29, 1888.

By direction of the acting Secretary of War, the following named officers of the Medical Department will report in person, on October 9, 1888, to the President of the Army Medical Examining Board, Army Building, New York City, for examination for promotion: Capt. Benjamin Munday, Asst. Surgeon; Capt. William O. Owen, Jr., Asst. Surgeon. Upon the completion of their examination to rejoin their stations. Par. 15, S. O. 225, A. G. O., Washington, September 27, 1888.

Lieut. Ogden Rafferty, Asst. Surgeon U. S. Army, will stand relieved from duty in connection with the Division rifle competition, the 7th inst., and under par. 6, S. O. 2, c. s., Hdqrs. Div. of the Missouri, will return to his proper station, Ft. Clark, Tex. Par. 5, S. O. 95, Hdqrs. Dept. of Texas.

THE EVOLUTION OF THE CYSTIC
KIDNEY.

Read in the Section on Practical Medicine, at the Thirty-ninth Annual Meeting of the American Medical Association, May 8, 1888.

BY I. N. DANFORTH, A.M., M.D.,
OF CHICAGO, ILL.

Synonyms:—Sacculated Kidney, Surgical Kidney, Pyonephrosis, Hydronephrosis

By "Cystic Kidney" I mean that condition of the organ in which it is more or less completely converted into a number of cavities, each cavity containing a fluid or semi-fluid matter, and possibly solid matter as well. The number of these cavities varies greatly, sometimes being limited to half a dozen or even less, sometimes reaching several hundreds. The size of the cystic kidney varies greatly: sometimes it is not enlarged at all; at other times it is enlarged to two or three times its normal dimensions.

The term "Evolution," although adopted as the title of this paper on the spur of the moment, seems to describe what occurs in renal cystogenesis most admirably, since it is really an "unrolling" or "unfolding" of the renal structure, as it slowly yields to the pressure of the fluid accumulating in the cysts.

It is the purpose of this paper to classify the causes of cystic kidney, and to briefly describe the mechanism by which each one produces its result. Of course in attempting to treat so large a subject within the time allotted to papers before this section much of detail must be omitted, but I think the essential facts can be stated without trespassing too much on your patience.

I think the causes of cystic or sacculated kidney may be classified as follows:

1. *Diathetic Causes*—with these varieties:

- a. Excess of saline elements of the urine.
- b. Tuberculosis.
- c. Carcinoma.

2. *Congenital Causes.*

- a. Floating kidney, with consequent twist of ureter.
- b. Congenital Hydronephrosis.
- c. Congenital degeneration of Glomeruli.

3. *Mechanical Obstruction* consequent upon disease of pelvic organs.

4. *Traumatic Causes.*

5. *Pathogenic Cysts.*

a. Dermoid.

b. Hydatid.

c. Cystic Metamorphosis.

1. Cystic kidney produced by "diathetic causes." By far the greater number of cystic or surgical kidneys occur during the active period of life, when the peculiar "diatheses" which lead to them are most likely to manifest themselves, and this is peculiarly true of the first group of cases—those produced by:

a. An "excess of the saline elements of the urine." In clinical experience we find that the "lithic acid" and the "phosphatic" diatheses are those which are most prolific of renal lesions, and their *modus operandi* is substantially the same. It is very easily explained. When assimilation and tissue waste are carried on in physiological proportion to each other—provided retrograde metamorphosis takes place in accordance with physiological laws—the urine is never "saturated" with solid matter, and no precipitation can take place in the renal tubules; but unfortunately these conditions do not always obtain. Certain grave departures from the normal course of assimilation and disassimilation occur, whereof the consequence is the super-saturation of the urine with saline elements. When this happens there can be but one result, namely, the saline elements, which are in greater excess, are precipitated within the lumen of the tubuli uriniferi, and mechanical obstruction of the invaded tubule follows. At first but a few particles of the given salt are thrown down, but these being angular or spiculate, easily insinuate themselves between the angles of the epithelial cells and thus become fixed at their point of lodgment. Two results now follow:

First, the foreign body, the saline particle, acts as a local irritant to the epithelial cells of the tubule, and they respond by entering into that pathological condition which we know as "cloudy swelling," which means that they enlarge and also that they throw off a glutinous secretion, which materially aids in obstructing the tubule; secondly, that the primary granule or crystal acts

as a point of attraction for other crystals, and thus a minute intra-tubal calculus is speedily formed. The tubule is now effectually occluded, but if the occlusion takes place below the convoluted portion, secretion of urine still goes on; meantime the tubule becomes inflamed, and then dilated, until a small cavity is excavated, which is filled by pus and urine, and the process of developing a multitude of similar cavities through the agency of similar causes goes on uninterruptedly, until the organ consists only of a series of cavities or excavations, from the size of a pin's head to that of a walnut, and we have the so-called "cystic" or "surgical" kidney. The calculi are not necessarily retained in the renal tubules; in point of fact, they are in most cases forced out of the tubules by the pressure of the urine accumulating above them, but not until the process of dilatation is well advanced, and the structure of the tubule is materially changed—so changed, indeed, that recovery is impossible. On the other hand, the calculi are not infrequently retained in the tubules, where they grow by accretion, until they acquire dimensions sufficient to produce deep-seated constant pain by their encroachments upon the renal tissues. In such cases the pressure of the calculi occludes many tubuli, and the result is at first a "multilocular" cyst, but later a single large cyst or cavity, because the intervening cyst walls are gradually broken down. Of late years many such cases have been radically cured by "nephrolithotomy," an operation which Henry Morris, of London, has done so much to establish.

b. "Tuberculous Kidney." Tuberculous disease of the kidney does not often occur, as a primary disease, although those who are much in the dead houses of our hospitals find occasional specimens. But whether the deposit be primary or secondary, its behavior is substantially the same. The tuberculous deposit is most common in the cortex, and generally each deposit clusters around some arterial twig. The artery thus isolated is gradually encroached upon, until its lumen is obliterated, and the blood supply of a small area is nearly or quite cut off. Hence, rapid disintegration of the involved tissue takes place, and the retrograde changes in the tubercle itself are hastened thereby. But meantime, the outlying connective tissue, true to its own instincts, has gradually increased, and has formed an impenetrable lateral wall against the escape of the softened and semi-liquid tubercle. There is now but one avenue of escape, namely, between the straight tubes which form the medulla, and project, as "papillæ" into the pelvis of the kidney. If the contents of the tuberculous cyst escape in this direction, we are likely to have a cone-shaped cyst, with the apex of the cone pointing towards the renal pelvis. But if the tuberculous matter remains imprisoned within

the cavity environed by the pathological connective tissue, we shall find a "cyst" or walled cavity filled with a putty-like or mortar-like material, which consists of tubercle corpuscles, pus cells, renal debris, and a sandy or gravelly "gritty" material, which represents the precipitated saline elements of the urine. Occasionally resorption of the liquefied contents of the cavity takes place, a solid matter remaining, perhaps to be subsequently mistaken for a true renal calculus, which of course it cannot properly be called.

c. "Carcinoma." In the adult, carcinoma of the kidney is almost never primary, and it is a well-known clinical fact that secondary manifestations of renal cancer are by no means common. Moreover, when secondary cancer of the kidney does occur, it is not generally followed by cystic degeneration; nevertheless this does occasionally happen, and in the following manner.

Cancerous deposits in the kidney occur sometimes as infiltrations, sometimes as rounded nodular deposits. In the latter case, each nodule is shortly surrounded and isolated by a fibrous capsule composed of hypertrophied connective tissue. By this process, the cancerous nodule is gradually shut off from its blood supply to an extent at least sufficient to induce early and rapid retrograde changes, particularly fatty or mucoid degeneration. Hence, the solid cancerous nodule becomes transformed into a soft pultaceous mass, or even into a dirty yellow or grayish fluid. This generally finds its way into the pelvis of the kidney, and thence into the bladder. It sometimes happens that our first intimation of renal cancer comes from a profuse discharge of purulent or bloody matter per urethram, which signals the fact that a cancerous nodule has undergone degeneration, and then "tunnelled" its way to the renal pelvis, whence its escape is direct and easy. It must (of course) be apparent, that each cancerous nodule which degenerates and escapes in the manner indicated, will leave a vacant cavity, or "cyst," and that the number of such "cysts" is equalled by the number of broken down nodules. Primary cancer of the kidney is a disease peculiar to childhood, "before the fourth or fifth year" [Morris.] It is almost always of the encephaloid type, and sometimes attains enormous proportions. I have seen one case in which the cancerous deposit distended the abdomen to an almost incredible degree, while the alimentary canal, the liver, and other abdominal organs were compressed and crowded so as to be hardly recognizable. In this case there were numerous cystic cavities with fluid contents of a dirty gray color, which were probably produced by the breaking down of isolated cancerous masses in the manner, and for the reasons already set forth. It must be admitted, however, that cystic excavations in cancerous kidneys are rare as compared with such excavations from

other causes; yet they have occurred, and doubtless will occur again; hence they merit a recognition in our text-books and lecture rooms.

2. "Cystic Kidney produced by Congenital Causes."

a. Migratory kidney with consequent "twist," or doubling of the ureter. I use the term migratory kidney advisedly, intending thereby to include both the "movable kidney" and the "floating kidney," whereof the anatomical and pathological distinctions are now well understood, and it is not necessary to discuss them here. Nor does it concern us particularly whether we are dealing with "movable" or "floating" kidney, since they are both, and about equally, subject to the accidents which result in a distended or sacculated kidney. The liability of the ureter to become twisted or doubled depends very much upon the range and movement which the kidney possesses. If the renal pedicle is short, and the kidney is confined in the post-peritoneal ileo-lumbar space, the danger is quite insignificant, although it does, even then, exist; on the other hand, if the pedicle is long and the organ is situated between the peritoneal folds which are known as the "mesonephron," the range of movement must necessarily be extensive, and the danger of ureteral obstruction must be much greater. There are two methods in which stenosis of the ureter may occur in "migratory kidney." First, "when the kidney drops forwards or downwards, as after long standing or sitting, the course of the ureter becomes so deflected and curved upon itself that the urine cannot flow along it." [Morris.]

A moment's reflection will make this clear. When the kidney "drops downward or forward," so as to bring the pedicle "taut," the ureter is made to describe an acute angle which has the effect of collapsing it, and producing more or less complete temporary occlusion. Meantime the secretion of urine goes on, the proximal portion of the ureter and the renal pelvis are in turn distended, the papillæ are pushed back and flattened, the calices are dilated, and the process of the "evolution" of the cystic kidney is fairly under way. But in a short time, owing to changes in the position of the body, or manipulation by the patient or his surgeon, or possibly by the distending force of the accumulating urine, the kidney is replaced, the ureter is rendered pervious again, and the accumulated urine disappears. Sooner or later the same series of events occurs again and again, each period of occlusion adding to the renal dilatation already existing, until the kidney is literally converted into a globular cyst, sometimes quite distinctly lobulated. Such cases used to be mistaken for ovarian tumors, but owing to our general increase of knowledge regarding abdominal tumors and their diagnosis, it is not likely to occur again. The twisted ureter acts in a precisely similar way, ex-

cept that the dilatation of the kidney goes on quite slowly, because the twist is generally no more than is accomplished by half a revolution of the kidney, and is therefore more frequently amenable to spontaneous restoration than the collapsed ureter above described. It is a clinical fact that nearly every migratory kidney is found more or less dilated when the organ is examined post-mortem, and that many an abdominal tumor which was a source of perplexity to the patient and her medical advisers, has been thus explained. I think a dilated migratory kidney is more likely to turn out a hydronephrosis than a pyonephrosis—at least such has been my own observation. I am quite well aware of the fact that the movable kidney is not always congenital, but, entertaining the opinion that the exceptions are exceedingly rare, I think I am fully warranted in including this class of cases among those of congenital origin.

b. "Congenital Hydronephrosis." This rare and singular form of renal lesion is so seldom seen, that but few of us can speak of it from experience. Yet it must be recognized as one of the causes of cystic kidney. It depends upon some malformation of the kidney or its appendages. As Morris and Dickenson observe, in the majority of cases, both kidneys are involved, and the cause lies in some fault at the cystic outlet of the ureter. But this is not always the case, since unilateral hydronephrosis is well-known among the surgeons, and several cases are recorded. The malformation which produces hydronephrosis may be at the pelvic extremity of the ureter, as when a valve-like fold of membrane closes the pelvic orifice of the ureter; or by some abnormality of the ureter itself—an obliquity, contraction, or arrest of development; or by occlusion, partial or complete, of the cystic orifice of the ureter. Or some abnormality of the renal vessels in consequence of which the ureter is compressed, may be the apparent cause. When both kidneys are involved of course an immediately fatal result must be the consequence; but when the disease is unilateral, the child is in no immediate danger. I have now a case of unilateral hydronephrosis under my care, the patient being an otherwise healthy boy 20 months old. The tumor occupies a large part of the abdominal area, and is so hard as to suggest a tumor with solid contents, instead of a hydronephrosis. Nevertheless, several weeks ago, when he was first presented at my clinic at St. Luke's Hospital, I drew off 40 ounces of urine by aspiration, using strict antiseptic precautions; but the cyst rapidly filled again, and in a week or ten days seemed as large as ever.

c. "General Congenital Cystic Degeneration." At rare intervals an infant is born or is instrumentally delivered with an enormously distended abdomen, due to the fact that the kidney has

been converted into a "congeries of cysts," a process of general cystic degeneration. Such a case is recorded in the *Medical Record*, for Jan. 21, 1888, and a few similar cases are on record. They are regarded, and probably correctly, as a peculiar form of cystic degeneration of malpighian bodies, but occasionally the convoluted tubules appear to be involved. In other words, the functional or potential portions of the kidneys only seem liable to this form of degeneration, and even then the process probably begins during intra-uterine life. The results are that the kidney is converted into a vast number of cysts, varying in size from those almost too small to be seen by the naked eye up to those as large as a hazelnut; that by the growth of these cysts and their progressive distension the kidney is greatly enlarged, and the abdomen greatly distended. The disease usually invades both kidneys, and is frequently associated with similar degeneration of other organs.

3. "Cystic Disease of the Kidney Produced by Mechanical Obstruction Consequent upon Disease of the Pelvic Organs."

a. Diseases of the bladder. Any form of cystic disease which produces thickening of its wall or intra-mural infiltration, so as to partially occlude the orifice of the ureters, is capable of inducing cystic kidney. And the cystic orifice of the ureter is very easily rendered impervious. It will be remembered that the ureter before opening into the bladder, passes for some distance between the walls thereof; hence the cystic orifice of the ureter is diagonal or valvular, an arrangement which retains the urine in the bladder when once it has arrived there. But when the bladder is thickened and corrugated by inflammation, or invaded by morbid growths, the cystic orifice of the ureter is more or less completely closed by pressure, and the entrance of urine rendered difficult and nearly impossible. Under these circumstances the ureter, the pelvis of the kidney, and finally the kidney itself, yield to the distending force of the retained urine, and a retention cyst, often of enormous dimensions, is the result. The diseases of the bladder most likely to produce cystic kidney are inflammation, carcinoma, sarcoma and tuberculosis.

b. Diseases of the uterus and its appendages. I have lately seen a case of double hydronephrosis in a woman almost 40 years of age, whereof the only discoverable cause was a compression of the ureters by a much enlarged and prolapsed uterus. The cervix uteri was enormously hypertrophied, tilted up against the bladder and fixed in this position by adhesions, so that the ureters were constantly although not severely compressed thereby. The consequence was a partial retention of the urine in the renal pelvis, and the slow but gradual extinction of the kidney, until nothing of the renal structure remained except a thin layer of cortical structure just beneath the thickened capsule.

Malignant disease of the uterus not infrequently produces cystic distension of the kidney; tumors of the broad ligament generally cause more or less complete stenosis of the corresponding ureter; ovarian fibroids have been known to produce the same consequences, and pelvic cellulitis, especially when followed by extensive suppuration, is very likely to be followed by gradual closure of one or both ureters, and its inevitable results. In short, any pelvic disease which is followed by pathological new formations, or the dislocation of the pelvic organs, may produce compression of the ureter and cystic kidney.

4. Traumatic Causes. The traumatic causes of cystic kidney cannot be formally classified. Any injury of the kidney may result in cystic disease—but how and why we cannot always explain. For example, I have lately seen the case of a young man who fell down a rough and precipitous hillside, thereby receiving a severe injury of the right kidney, which was followed by pain, tenderness and hæmaturia. These symptoms shortly subsided and the patient regarded himself as quite well. Yet the kidney remained slightly tender; he had occasional but not severe attacks of nephralgia; and four years after the injury he died after nephrotomy, the kidney being an enormous multiple abscess. I have seen several cases of cystic kidney attributable to traumatic causes, although it is impossible to explain how an injury to an organ should set in operation that train of pathological events which result in a multiple cyst. This fact we must recognize in all its pathological, diagnostic and therapeutic bearings.

5. "Pathogenic Cysts."

a. "Dermoid Cysts." The dermoid cyst, so far as I am aware, has never been found in the human kidney. It has without doubt occurred. They have repeatedly been found in the kidneys of the lower mammalia, and there is no reason why they should not be found in man. On the other hand, reasoning from the standpoint of analogy, and having due regard for the teachings of the laws of pathology, so far as we understand them, we have every reason to believe that the dermoid cyst has invaded the human kidney and will do so again. Therefore I am of the belief that the dermoid cyst ought to be regarded as one of the forms of disease to which the kidney is liable, in spite of the fact that the opinion cannot yet be authenticated by experience.

b. "Hydatids." In the language of Roberts, "Hydatids of the kidney are comparatively rare; they are much less common than hydatids in the liver, and even in the lungs; but they are more frequent than hydatids in the other organs and tissues of the body." These cysts pursue in the kidney precisely the same course that they do in other organs, except the intestinal canal. That is, they become filled with echinococci by continuous endogenous development until a parent cyst of

large, and sometimes enormous proportions, is the result. But the echinococci never advance beyond the first stage of development, and their reproduction may be arrested; hence it follows that an hydatid cyst may remain in the kidney for years without exciting any pronounced symptoms, or involving their host in any imminent danger.

c. "General Cystic Metamorphosis." Although this is a rare form of disease, nearly all recent writers describe it and produce illustrative cases. The kidney—or generally both kidneys—are enlarged and transformed into a multitude of cysts, which range "from the size of a pin's head to that of an orange." (Roberts.) They contain a reddish or yellow limpid fluid, which is always highly albuminous, and contains epithelial cells much changed and degenerated by maceration. According to the best observations of the best observers, they are derived both from altered and degenerated malpighian bodies, and altered and degenerated segments of convoluted tubes.

The cause of this peculiar analogue of the congenital cystic kidney is but little understood, but it is probably of the nature of collagenous degeneration of the renal cells.

In conclusion, I have to express my regret that so much remains to be learned concerning cystic disease in general, and of the renal cysts in particular, and to add the hope that in the near future our knowledge will be more definite and accurate upon this as upon all other subjects which interest the working pathologist.

ABSTRACTS OF CONTRIBUTIONS TO TERATOLOGY.

DEFINITION OF TERATOLOGY. GIANTS AND DWARFS. CLASSIFICATION OF MONSTROSITIES. FOUR-LEGGED CHILD, J. MYRTLE CORBAN. SIAMESE TWINS. HUNGARIAN SISTERS. SOUTHERN NIGHTINGALE. SOUTH CAROLINA TWINS. MILLIE AND CHRISTINE. JOHN ALLEN. HERMAPHRODITISM. MISS EMILY LAUNDRY, THE LOUISIANA BEARDED GIRL.

BY JOSEPH JONES, M.D.,

PROFESSOR OF CHEMISTRY AND CLINICAL MEDICINE, MEDICAL DEPARTMENT TULANE UNIVERSITY, OF LOUISIANA; VISITING PHYSICIAN OF CHARITY HOSPITAL, NEW ORLEANS, LA.

DEFINITION OF TERATOLOGY.

The word Teratology, which we owe to Geofrey St. Hillaire, literally means the *Science of Monsters*, and in the present article we shall apply the term to the *doctrine of congenital deformities*. Teratology, in a scientific sense, constitutes a part of *Pathological Anatomy*, which comprises all the anomalies of the organization; those which occur during *intra-uterine* life are called *congenital*, and those which arise during *extra-uterine* life, *acquired*. What are commonly called *monsters* are most generally referable to the former; that, is to the imperfections of the primitive formation.

Teratology, therefore, as a department of Morphological Science treats of the deviations from the normal development of the embryo.

The term *embryo* is commonly limited in human anatomy to the ovum in the first three months of its *intra-uterine* life, in which it is still developing or acquiring the rudiments of its form; the term *fetus* being applied to it in the subsequent months during which the organism grows in the lines of development already laid down.

It is mostly in the first, or embryonic, period that these deviations from the normal life occur, which present themselves as monstrosities at the time of birth.

CLASSIFICATION OF MONSTROSITIES.

The most usual grouping originally suggested by Buffon (1800) is into *Monstra per excessum* and *Monstra per defectum*, and *Monstra per fabricam alienum*. But some writers have placed the more simple cases of excess and defect side by side, and separate the double monsters from the single; the theory of the former being a distinct chapter in Teratology.

The origin of monstrosities has been referred to two main causes:

1. To the original malformation of the germ.
2. To the subsequent deformation of the embryo by causes operating on its development.

It is evident that giants and dwarfs are not referable to the action of these causes, because in both forms of monstrosity nothing peculiar may be noticed at birth. The infant of the future giant may be small and well-proportioned, and that of the dwarf large and well-proportioned.

CAUSES OF CONGENITAL ANOMALIES.

1. Original malformation of the germ.
2. Deformation of the originally well-formed germ.
3. Diseases of the ovum and fetus.
4. Imperfect development of the fetus from some remote or unknown cause.

CLASSIFICATION OF MONSTROSITIES.

1. Malformation of the ovum.
 - (a). Molabostryoides.
 - (b). Separation of the placenta into lobes or cotyledons.
 - (c). The vesicles of the umbilical cord are separated near the placenta, and meet at a considerable distance from it.
 - (d). The umbilical cord too long.
 - (e). The umbilical cord too short.
 - (f). Absence of one of the umbilical arteries.
 - (g). Increased number of the vesicles of the cord.
 - (h). Persistence of the umbilical vesicle.
 - (i). Constriction of the umbilical cord.
 - (j). Umbilical cord too thick.

MALFORMATION OF THE FŒTUS.

- (A) Monstrosities produced by the arrest of development.

1. Non-closure of the anterior parts of the body: (a) fissure of the whole anterior wall of the body; (b) fissure of the thorax; (c) fissure of the anterior abdominal wall; (d) fissure of the pubic and hypergastric regions; (e) cervical fissure; (f) fissure of the face.

2. Fissure of the skull: (a) want of the brain and exposure of the whole basis of the skull; (b) the denuded surface of the *basis cranii*, occupied by a spongy substance instead of brain; (c) the surface of the *basis cranii* only partially denuded, a spongy tumor occupying the place of the brain; (d) the skull flat, but having an opening through which the brain protrudes, as a hernia.

3. Fissure of the back part of the body; (a) Hydrorrhachis, and spina-bifida.

4. Hydrocephalus congenitus.

5. Acephalæ, or fœtus without a head.

6. Want and defective formation of the trunk—*aconia*.

7. Defective formation of the extremities.

8. Cyclopia.

9. Deficiency of the lower jaw—*monoia*.

B. MONSTROSITIES PRODUCED BY AN EXCESS OF DEVELOPMENT.

1. Fœtus in fœtu.

2. Double monsters—heteradelpha.

3. Double monsters; (a) anterior duplicity; (b) lateral duplicity; (c) inferior duplicity; (d) posterior duplicity; (e) superior duplicity.

4. Triple monsters.

FOUR-LEGGED CHILD, J. MYRTLE CORBAN.

One of the most remarkable instances of monstrosity which has come under my observation is that of the four-legged child (infant), J. Myrtle Corban, examined by the late Professor Paul F. Eve and the writer, in Nashville, Tenn., June 16, 1868.

The following, Figure No. 1, represents the appearance of this monstrosity.

FIGURE 1.—Four-legged female infant, J. Myrtle Corban, from photograph taken in Nashville, Tenn., June 16, 1868, about twenty years ago.

The following description of the infant, J. Myrtle Corban, was prepared jointly by the late Professor Paul F. Eve and myself, June 16, 1868.

INVESTIGATION OF THE FOUR-LEGGED CHILD, J. MYRTLE CORBAN.

Nashville, Tenn., June 16, 1868.—The undersigned, in response to the request of a number of physicians and the relatives and friends of the unfortunate subject of this investigation, give the following testimony: The infant, J. Myrtle Corban, has four legs and two distinct external female organs of generation, with two external openings of the urethra and two external openings of the double rectum. The external genito-urinary organs are as distinct as if they belonged to two separate human beings. The feces and urine are passed (most generally simultaneously, particularly the urine), from both external urinary and intestinal openings, situated respectively between the left and right pairs of legs.

The head and trunk are those of a living, well-developed, healthy, active infant of about five weeks, whilst the lower portion of the body is divided into the members of two distinct individuals, near the junction of the spinal column with the *os sacrum*. As far as our examination could be prosecuted in the living child, we are led to the belief that the lower portion of the spinal column is divided or cleft, and that there are *two pelvic arches supporting the four limbs*, which are situated upon the same plane.

Photographs of this infant have been made by the advice and under the supervision of one of our number.

The reality in this case surpasses expectation, and we are of the opinion that this interesting *living monstrosity* exceeds in its curious manifestation of the powers of nature in abnormal productions, the celebrated "Siamese Twins."

JOSEPH JONES, M.D.,

Prof. of Phys. and Path., University of Nashville.

PAUL F. EVE, M.D.,

Prof. of Surgery, University of Nashville.

FURTHER REMARKS BY PROFESSORS JONES
AND EVE.

Josephine Myrtle is the third offspring of W. H. and Nancy Corban, aged 25 and 34, the wife being the senior by nine years. They are so much alike in appearance, having red hair, blue eyes and very fair complexion, as to produce the impression of their being blood kin, which, however, is not the case. Mrs. Corban is from North Alabama, had borne one child to a former husband, the child having dark coloring, and resembling mostly the father, who had black hair and eyes. Her three children are all girls, the one already alluded to, now 6 years old, another 3, and this *infant monstrosity*, now to be more minutely described, born the 12th of May, 1868, in Lincoln county, Tennessee, five weeks ago.

Mr. Corban is a Georgian, served in the Confederate army through the war, and was severely wounded in the right arm and left hand. The parents are in fair health, though the mother is *anæmic*. She recollects no fright or disturbance during her last pregnancy. The presentation was fortunately the head, which accounts for the preservation of the life of the child. It would be curious to speculate on the trouble which might have been produced had the feet or breach presented, while the result, in all probability, would have proved fatal to the infant, and possibly to the mother. Mrs. Corban says that there was nothing peculiar in the labor or delivery. When three weeks old the child weighed ten pounds. It now nurses healthily, is thriving well, and we saw it urinate simultaneously, between the *two pairs of labia of the two vagina*, situated about six inches apart. From the crown of the head to the *umbilicus* measures twelve inches, and from this point to the toes of the right and left external feet, eleven inches. From the *umbilicus* up all is natural and well-formed; all below this extraordinary and unnatural. An inch below the navel is a mark of an apparent failure for a second one. There are four distinct pretty well developed lower extremities. They exist in pairs on both sides of the median line which resembles the cleft of an ordinary pair of legs; but here there are no marks whatever of *anus* or *genital* organs, and upon pressure we discover no *os coccygis* or *sacrum*. The outer legs of both sides are the most natural of the four (though the foot of the right one is clubbed), but are widely separated by the two supernumerary ones, which are less developed, except at their junction with the body, from which they taper to the feet and toes more diminutive, and which are turned inwards. One toe is bifid on the left extra inward extremity. At birth these extra legs were folded flat upon the abdomen. We are led to believe that there are *two uteri as well as two recti*; in fact that the pelvic organs are double. Of course a minute dissection would alone expose the true condition of these parts.

Should this infant reach maturity and the internal generative organs be double, there is nothing to prevent conception on both sides. The first difficulty will, however, be in her walking. The outer, or external legs, may be used for progression; the inner, or intumed ones, probably never. These might be successfully amputated at the knees, or higher up.

One of us recollects being in London, in January, 1830, at an exhibition of the Siamese Twins, when Sir Astley Cooper gave an opinion adverse to an operation with a view to separate them, but which has always appeared to us feasible and without much risk of *peritonitis*; an operation, too, which should undoubtedly be performed in case of the death of one of them, for no medical man believes in the vulgar impression that they

must die simultaneously. In the present case all surgical interference, is of course, out of the question, except that alluded to—removal of the extra legs.

Cases somewhat similar to the above have occurred and been described. Rokitsansky refers to two completely distinct bodies conjoined at their *ossa sacra* or *coccyges*, as in the well-known Hungarian sisters, Helena and Judith, born in 1701, who survived their twenty-second year.

Geoffrey St. Hilaire alludes to cases of a trunk with two heads, some even Janus-like, having four upper and four lower extremities.

The case, however, recalled most vividly by Josephine Myrtle, is that of Rita-Christina, well-known in Europe, and accurately described in this country years ago by Prof. Meigs. In this wonderful instance there were two heads, two necks, four arms, but only two legs; and was thus the reverse of our case. From the *umbilicus* down there was one well-formed child, but above this all the organs were double; in reality there existed two beings. The rectum and bladder were common to both, but all else in the trunk was double and distinct. One would sleep while the other played, etc., for they had *two spinal marrowes, two brains, two hearts*, but the last two occupied a common *pericardium*. Unfortunately, after surviving a little over a year, one sickened and died, when the other, then in health, instantly expired.

Rita and Christina were born in Sardinia, 1829, and described by Dr. De Michaelis, Professor of Surgery in the Royal University of Sassari, and lived eighteen months.

The late Prof. J. C. Warren, of Boston, first described the Siamese twins brothers, when purchased of their mother by Capt. Coffin and Mr. Hunter (joint owners), and brought to that city, in 1829.

The infant J. Myrtle Corban thus described by Professor Paul F. Eve and myself in 1868, appears to be one and the same individual as the lady described in the following extract from the proceedings of the Alabama State Medical Association, published in the daily papers of Montgomery, Ala., April 13, 1888:

"A wonderful case of deformity or freak of nature has come to light in Alabama, which is without a parallel in history. Dr. Lewis Whaley, of Birmingham, read a paper presenting the strange case to the State Medical Association April 12, 1888. The phenomenon is in the person of Mrs. Clinton Bicknel, a white lady who resides in Alabama. She is a perfectly double woman in body and lower extremities, having four legs, four feet, and two distinct sets of physical organs. Dr. Whaley was called to see this lady some weeks ago, and was nonplussed by her strange sickness and symptoms. He called in two other physicians to assist him in making a diagnosis of the case. They found that Mrs. Bicknel was in a state of pregnancy on one side only—the left side. They

found it necessary to produce an abortion, and she gave birth to a well-formed child. Sometimes, the doctors say, the lady suffers with diarrhoea on one side and constipation on the other.

"She was formerly Miss Josephine Myrtle Corban. At the age of 18 she married Clinton Bicknel, and is now 20 years of age. At present she enjoys good health. Photographs of the lady were presented to the Association."

From a letter of May 17, 1888, which I have recently received from Dr. E. H. Sholl, of Birmingham, President of the Alabama State Medical Association, I am informed that "the lady, Mrs. Bicknel, of Blount Co., Ala., is the Myrtle Corban of days gone by, *attractive in face, physically well, and able to attend to all her household duties.*"

SIAMESE TWINS.

The subsequent history of the Siamese Twins shows that the eminent surgeon, Sir Astley Cooper, was correct in his opinion adverse to an operation to separate them. The Siamese Twins died in 1874, at the age of 60. They were joined by a thick fleshy ligament, from the lower end of the breast-bone (xyphoid cartilage), having the common navel in the lower border. The anatomical examination showed that a process of peritoneum extended through the ligament from one abdominal cavity to the other, and that the blood-vessels of the two livers were in free communication across the same bridge. There are one or two cases on record in which such a ligament has been cut at birth, one at least of the twins surviving.

Twins may be regarded as the physiological analogies of double monsters, and from cases like the Siamese Twins, in which the monsters have come very near to being two separate individuals, there are all grades of fusion of two individuals into one, down to the condition of a small fragment or parasitic body in a well-grown infant, *fetus in fetu*.

If we refer Josephine Myrtle Corban to the class of *Heteradelphia*, or *double monsters*, in which one of the fetuses is more or less perfect, and the other merely an appendix, it is difficult if not impossible to determine the original and perfect fetus from the appendix. It looks rather as if, during the development of the blastoderm or ovum, there had been a true fusion or division of the spinal cord, of the intestinal tube, and of the genito-urinary organs.

I have recently examined the case of a white lad about 14 years of age, a native of Louisiana, who was supposed to have scrotal hernia; but I found upon careful examination no varicocele and no hernia, but instead three large, well-developed testicles.

In another case, a married man "*who had never had but one testicle*," I was called to see him in great pain, with rapid pulse and incessant vomit-

ing. The attendant physician had pronounced the case to be one of strangulated hernia, and was preparing to operate; to which procedure, however, the patient objected. Upon careful examination I found a hard tumor about 1 inch in length and $\frac{3}{4}$ inch in diameter, in the right inguinal region. By careful taxis, I brought the testicle out of the ring into the scrotum, and left the patient rejoicing in his possession of two testicles.

These facts illustrate the difficulty of forming correct conclusions in the absence of the most rigid examination. In the case of the infant J. Myrtle Corban, a rigid examination of the uterine and pelvic organs was impracticable.

The pelvis is one of the commonest regions for double monsters to be joined at, and, as in the head and abdomen, the junction may be slight or total.

The Hungarian sisters, Helena and Judith, (1701-1723) were joined at the sacrum, but had the pelvic cavity and pelvic organs separate. The same condition obtained in the South Carolina negresses Millie and Christine, known as the two-headed nightingale, and in the other recent case of the Bohemian sisters, Rosalie and Josepha.

South Carolina Negresses, Millie and Christine; Two-headed Nightingale.—I had the opportunity of examining these South Carolina twins during their exhibition in New Orleans, about the year 1869. There was evident fusion and decussation of the nervous elements of the spinal cord in the sacral region. Pressure, pricking or pinching of the lower extremities of either twin was distinctly felt by the other. This was not the case with the upper extremities. Impressions made on the hands, arms, head or neck of one twin were not felt or recognized by the other.

The following is an accurate representation of this interesting double monster, or female negro twins united at the sacrum.

FIGURE 2.—SOUTH CAROLINA TWINS, OR NEGRO
DOUBLE-HEADED NIGHTINGALE, "MILLIE
AND CHRISIE."

"Millie and Chrissie" were quite intelligent and sang some songs with good effect, and it was affirmed that they were but one being with but one common genital organ.

The Carolina twins, "Millie and Chrissie," were united by their lower lumbar vertebræ, sacrum and coccyx. There is a single anus and a single vulva, but two hymen and two clitorides, but very probably two vaginae and two uteri.

The Hungarian Sisters, Helena and Judith, had but one vagina, although the upper part of that organ was divided into two, and the two intestines met in a single anus, placed between the four thighs. The Bohemian sisters, Rosalie and Josepha, in whom there is a junction of the posterior wall of the pelvis, present apparently a single anus, but a double vagina.

The four-legged child, Josephine Myrtle Corban, and the South Carolina twins, Millie and Christine, may be referred to monstrosities or malformations by excess.

Two ova may be formed in one Graafian vesicle, for double-yolk eggs are well known; but there is no evidence to show that there would form a double monstrosity; thus Professor Allen Thomson found, on incubating a dozen of such eggs, that not one produced a double embryo, while Wolff observed two completely separate fetuses developed upon a single yolk. The arrival of two impregnated ova in the uterus at the same time, will probably give rise not to double monsters, but to twins, and their fusion seems almost impossible. Embryologists have thus been led to the opinion that monsters by excess depend chiefly on an error of development taking place in a single germ; and this idea has been supported by the fact that Allen Thomson has shown that in birds two primitive germs may be found in one yolk, and in one *area germinativa*; and in this way the most complete cases of double monstrosity can be explained. And in confirmation of this theory, the researches of Tireboullet may be cited. This observer has seen, instead of the single budding of the blastoderm, which is ordinarily developed into the embryo of the fish, two, or even three, buds marked off; and these, during the process of development, would meet at some point and in this manner produce distinct parts of embryos, when they are separate, whilst a corresponding region of a single organism only would be found at the point of junction. According to the mode and extent of the blastodermic buds, the monsters would vary; and so would be derived all the different varieties, from a duplicity of the face or head, the upper or lower extremities, to such extreme cases as those which we have cited, as the Hungarian sisters, the Siamese twins, and the Carolina twins.

The following case presents a remarkable blending of the male and female sex:

This singular and distressing case of malformation of the genital organs must be referred to an arrest of the development of the testicles during fetal life.

JOHN H. ALLEN, OF ILLINOIS.

Singular and Distressing Case of Malformation of Genital Organs.—The following curious case of malformation of the genital organs came under my observation during the past 10 years, and was brought before the medical class of the University of Louisiana.

J. H. Allen, aged 23, height 5 feet 7 inches, weight 150 lbs., native of Illinois, U.S.A. Dresses in male attire. Voice fine, like that of a woman. Face full and smooth, without any sign of a beard. Features resemble more nearly those of a woman. Mammæ larger than is usual in men, but smaller than those of women. Nipples small, well formed, with a distinct dark areola. No hairs around the mammæ or on the breast, which is smooth like that of a woman. With the exception of the pubes and scalp, the body is devoid of hair. The general form is that of an athletic masculine woman. Hips full, and wider than chest. Circumference around hips, 39½ inches; circumference of chest during full inspiration, 35 inches; circumference of chest during expiration, 32 inches. Has a small, well formed penis, ¾ths of an inch in length, and 1⅓ths inch in circumference, with glands, frænum, prepuce, and urethral opening. The patient discharged urine through this opening in my presence. Below the penis there is a slight swelling or fulness of the integuments with a distinct raphe or tramis, like that which divides the scrotum in men into two parts, extending from the anterior part of the anus to the extremity of the penis. Upon careful examination, however, no testicles can be felt on either side of the raphe, or within any portion of the fulness which corresponds to the scrotum. A careful examination by the introduction of the finger into the rectum, whilst firm pressure was made upon the abdomen above the pubes, failed in disclosing the existence of any body corresponding to a uterus. This examination, however, was not entirely satisfactory, on account of the fulness of the abdominal walls. Buttocks and thighs full and round. The upper line of the hairy pubes terminated abruptly, without any fading off in the median line, as in the male.

I gathered the following facts from this individual:

Father of John H. Allen a strong, healthy man, native of Boston, Mass.; mother a healthy, well-formed woman, native of Pennsylvania; parents have had nine children, eight of whom were well-formed; the eldest, a woman of 25, has had three well-formed children. The subject of this exam-

ination is the second child. The third child, aged 21, is a woman and married. The remaining children were three boys and three girls; and of this number one girl and two boys have died; one boy, 13 years of age, well-formed, living; two sisters, aged respectively 10 and 2 years, living.

The subject, J. H. Allen, has always been called Johnny, and was dressed as a boy from early childhood. Was not aware that there was anything peculiar in his organization until after the age of 12 years had been attained; upon one occasion, when swimming with a number of boys, it was discovered that he was not formed like a boy, and was called by his companions "a half boy and half girl." Attended school up to the age of 17, and since this time has followed the occupation of "bar-tender." Has been taken up by the police upon several occasions as a woman in man's clothing, and after being examined has been released as a "nondescript," but has always been compelled by the authorities to wear male clothing.

Prefers the male sex, never loved a woman, regards women as sisters; has loved a man devotedly, but always feared to divulge the passion. Loves the dress of a woman and despises that of a man. When insulted feels like crying, as is common with women. When traveling on the Mississippi boats has several times been approached by rough men, who threatened rape, declaring that Johnny was a woman in man's clothing. Upon one or more occasions has excited the jealousy of women, on account of the supposed attentions of their husbands. When acting with a stock company, in the character of a woman, the wife of one of the actors who played the part of lover to Johnny, was excited to violent jealousy.

When dressed in women's clothing neither men nor women ever suspect Johnny to be anything but what the dress and general appearance would indicate.

The condition of Johnny is most distressing; it is with great difficulty that a position or work of any kind can be secured or retained, on account of being suspected as a woman in man's clothing; and when traveling in strange places, or when walking upon the streets at night, is liable to insult and arrest. His most earnest wish is to be allowed to wear women's clothing, and to enter the stage as an actress.

As far as my inquiries extended, there has not as yet been any periodic discharge of blood from the urethra, rectum, stomach, or nostrils, which could be considered as connected with the menstrual function, although the patient described certain vague and uncomfortable feelings in the abdomen and certain periodic changes of the complexion and features.

The following figures 3 and 4 represent the body and thighs and genital organs of John H. Allen.

We have in this case of John H. Allen a strange

admixture of the male and female natures. The male character is represented by the minute but well-formed penis, whilst the form of the body, as shown by the photographs which I have caused

FIGURE 3.—JOHN H. ALLEN.

FIGURE 4.—JOHN H. ALLEN.

to be taken, approached more nearly to that of a female. The instincts were in like manner feminine. This case resembles a *hermaphrodite* in one sense, and in another a *natural eunuch*. In striking contrast to the case of John Allen we have the following:

MISS E. LAUNDRY, THE BEARDED GIRL OF
LOUISIANA.

This hairy and bearded girl was a native of St. Laundry Parish, Louisiana, where she was born in the year 1873, and was exhibited during the last year to the public, accompanied by her mother, Mrs. Laundry. Her father, who still resides in Terrebonne Parish, is a farmer. Miss Emily Laundry was covered with a remarkably thick growth of soft light brown hair, from head to foot, and possessed a full beard of brown hair. Her upper lip was covered with a light moustache. Eyes brown, hair of head light brown and abundant.

The following is an accurate representation of Miss Laundry:

FIGURE 5.—Miss Emily Laundry, the bearded and hairy girl of Louisiana, 1887.

It will be seen that Miss Laundry, at the age of 13, when this photograph was taken, presented the appearance of a stout, plump, well formed young woman, well developed mammae and rounded hips.

Miss Laundry was well formed and well grown for her age. The preceding engraving represents her in the 13th year of her age, and shortly before her death, which occurred in Detroit, Mich., from diphtheria contracted in Minneapolis, April 20, 1887. The body was embalmed and shipped to New Orleans, where it arrived April 22, 1887.

Through the courtesy of the undertaker I was enabled to make a careful examination of the embalmed body, and found that the mammae and female organs were characteristic, and that with the exception of the beard, moustache, and excessive

growth of hair, she was what she was represented to be, a well formed young woman.

A relative informed me that Miss Laundry had menstruated at three years of age, and that when her mother was pregnant she constantly gazed upon an oil painting of Christ, whose face was represented with a full beard. The child was born with a beard, and the mother attributed this "freak of nature to the effects of the portrait of Christ." On her father's side many of the males were said to be characterized by an excessive growth of hair.

The singular case of John Allen may be referred to the class of *hermaphrodites*.

Under the head of Hermaphroditism, or Hermaphrodisism, may be included: 1st. Some varieties of malformation in which the genital organs and general sexual configuration of one sex approach, from imperfect or abnormal development, those of the other.

2d. Other varieties of malformation in which there actually coexist, in the body of the same individual, more or fewer of the genital organs and distinctive sexual characters, both of the male and female.

Hermaphroditism may be regarded as due to a failure of purpose, or to an uncertainty in the *nisus formativus* at an early stage of development. There is a period of time, following about the eighth week, up to which the embryo may develop either the reproductive organs of the male, or the reproductive organs of the female; in the vast majority of cases the future development and growth are carried out on one line or the other, but in a small number there is an ambiguous development, leading to various degrees of hermaphroditism, or doubtful sex. The primary indecision, so to speak, affects only the ovary or testes respectively, or rather the common germinal ridge, out of which either may develop; the uncertainty in the embryonic ridge sometimes leads actually to the formation of a pair of ovaries and a pair of small testes, or to an ovary on one side and a testes on the other; but even where there is no such double sex in the essential organs, as in the majority of hermaphrodites, there is a great deal of doubling and ambiguity entailed in the secondary or external organs and parts of generation. Those parts which are rudimentary or obsolete in the female, but highly developed in the male, tend in the hermaphrodite to be developed equally, and all of them in an imperfect manner. In some cases the internal organs of one sex go with the external organs of the opposite sex.

It is possible that in the case of John Allen the ovaries and uterus were developed partially, whilst the only representative of the male organs is the diminutive but well formed penis; hence the strange mingling of the male and female natures, the latter predominating in strength.

156 Washington St., 4th Dist., New Orleans, La., 1888.

THE TREATMENT OF SACRO-ILIAC TUBERCULOSIS.

Read in the Section on Surgery at the Thirty-ninth Annual Meeting of the American Medical Association, May, 1888.

BY WELLER VAN HOOK, A.B., M.D.,
OF CHICAGO, ILLINOIS.

Time will not permit a discussion of the history, pathological anatomy, semeiology and diagnosis of tubercular disease of the sacro-iliac joint. The history of the study of the disease is intimately associated with that of "tumor albus" elsewhere, and affords a subject of corresponding interest. The semeiology and diagnosis are of importance not only on account of the fact that the disease has peculiarities of its own, but also because there are points of similarity between the signs of sacro-iliac disease and those of sciatica, Pott's disease, and especially of morbus coxarius, that may render its diagnosis exceedingly difficult, and perhaps in some cases impossible. The subject of the treatment of the disease, however, will be presented to you, as being perhaps of more general interest.

The clinical characteristics of tuberculosis at the sacro-iliac joint partake of all the general characteristics of tuberculosis of other joints. The sense of deep boginess over the joint indicating chronic inflammatory involvement of the deep structures, and cedema of the soft parts above are present here as well as in morbus coxarius. The loss of function, the pain on pressing the bones together, the tenderness over the joint cavity, the change in attitude, the tumefaction, and finally the sense of fluctuation yielded by fluid exudates are common here as in tuberculosis of the knee or ankle. In older cases in which cold abscesses have formed and have opened outward, we find fistulae, running in a great variety of directions from the starting point in the joint itself.

But from the symptoms of the disease we must endeavor not only to determine its pathological nature and its seat, but also its clinical tendency. For upon this will depend not only our prognosis, but also our treatment. We cannot here pause to discuss the movements effecting this tendency. Suffice it to say that they are comprised under the heads of the resisting power of the tissues and the invading power of the microbes. The anatomical evidence of supremacy is, in the case of the tissues, cicatrix formation; in the predominance of microbic power, local extension of tubercular granulations, and often the formation of cold abscesses. But, while we have learned from Koenig and others that osteal granulation-mass foci have a general tendency to peripheral extension; that wedge-formed sequestrum foci chiefly tend to spread tuberculosis toward the base of the wedge; and that some cases of synovial tuberculosis tend to dry granulation, others to abscess formation, we must confess with regret that we

cannot clinically diagnosticate all of these pathological conditions, and hence cannot from these data determine the tendency of the disease. We are compelled, therefore, to limit our deductions, after locating the disease, to a determination of its tendency from a single symptom, viz., the presence or absence of cold abscesses; for if time permitted, it would be easy to show that the other symptoms are of little prognostic value.

Of thirty-eight cases of sacro-iliac tuberculosis with abscess formation that I have collected, only three have recovered without some sort of operative interference.

On the other hand, with the observance of hygienic laws, together with the application of complete mechanical rest, sixteen out of a total of seventeen collected cases without abscesses went on to complete recovery, the only death being due to an older suppurating tuberculosis at the hip-joint. If, therefore, under similar conditions, 92.1 per cent. of the cases with abscesses die, while 94.1 per cent. of the cases without abscesses recover, we are entirely justified in concluding that the abscess cases have a very strong tendency to a lethal termination, while the cases in which abscesses do not develop tend still more strongly to recovery.

But though the cases without abscesses tend to recovery, we have numerous examples to prove that cases originally devoid of abscesses can proceed, chiefly under imperfect treatment, to local extension, abscess formation, and eventually to death.

Again, the moist form without mixed infection—even where abscesses are present,—may end in recovery, as doubtless occurred in Hilton's case already cited, by resorption of fluid matter and encapsulation of the focal detritus. Instead of the fluid being resorbed it may be discharged externally, the original focus being enclosed as before in a scar.

Death occurs in the moist form from sapræmia or from septicæmia, due to mixed infection; from simultaneous or intercurrent local tuberculosis elsewhere, as in the intestines, peritoneum, and lungs; or from general military tuberculosis brought about by tubercular infection of the blood itself.

Previous to the period when radical operations came in vogue for the treatment of tubercular arthritis, the treatment of sacro-iliac tuberculosis was on a par with that of other joints. Erichsen, in his celebrated clinical lecture of 1859, describes the treatment as properly including, besides internal remedies, rest with counter-irritation during the period prior to abscess-formation and opening of abscesses by valvular incision when they are large and chronic. He distinctly stated that operative interference was out of the question. In 1853, however, six years earlier, Prof. L. A. Sayre, of New York, had operated on a

case in a child by opening the joint posteriorly and gouging out carious bone. The child recovered and grew to manhood. This case has not been published in detail, and was communicated to me by Prof. Sayre. So far as I can ascertain, it is the first case in which *évidement* was practiced.

The advice of Erichsen, however, was followed out almost universally; for the formation of cold abscesses was regarded as a symptom of most desperate import. This was not unnatural, inasmuch as radical operative interference was positively forbidden, and the eventual occurrence of mixed infection seemed inevitable, with its long train of septicemic symptoms, finally ending in death. So great was the dread of mixed infection that, in the absence of occlusive antiseptic dressings, only valvular incisions were made to allow the tubercular matter to escape. Such incisions were generally sealed up with collodion.

It is only in the last five years that operators have begun to consider seriously the question of radical treatment of the disease, operations having been performed by Tiling, of St. Petersburg, in 1883, and two last year by Gant, of England.

Those statistics already referred to when speaking of the tendency of sacro-iliac disease, are of vast importance in determining the nature of our treatment. For if 94.1 per cent. of the cases without abscesses recover, we learn two important facts, namely: that the treatment under which these recoveries took place is well nigh perfect as regards mortality, and that it behooves us to endeavor, by all the means in our power, to prevent the supervention of abscess-formation, after which there are only 7.9 per cent. of recoveries without operation. The cases that give a favorable result were all treated by rest very carefully carried out. The sacro-iliac joint cannot rest when the weight of the body is imposed upon the ischial tuberosities, or upon the heads of the femora. Hence to secure absolute immobility the patient must lie upon the back. This was Hilton's treatment. Prof. Sayre makes a thorough cauterization over the joint and uses extension. After a variable period, depending on the severity of the symptoms, he places his patients upon crutches, using a high heeled shoe on the sound side, and, to keep up extension, puts a heavy weight on the heel of the shoe used on the diseased limb. A diagnosis having been reached sufficiently early, these details of treatment certainly recommend themselves to us on account of the brilliant success with which Sayre has carried them out.

But when abscesses have formed, the treatment by rest alone has given such dismal results that we cannot wonder at the despair of Erichsen and many other writers, who regarded sacro-iliac disease as one of the most fatal in the nosological catalogue. Considering the number and variety of dangers awaiting the patient suffering from cold abscesses, we would be compelled to sanc-

tion even the most radical curative measures.

Sacro-iliac tuberculosis attended by abscess formation, I believe, admits of radical operation by no means grave in a very systematic manner, according to indications quite simple. The abscesses are compelled, by anatomical peculiarities, to pass either immediately into or out of the pelvis; that is, either anteriorly or posteriorly. This direction depends largely on the point at which the disease originated, whether at the anterior or posterior portion of the joint. Consequently, when we find originally intra-pelvic abscesses, we may justly assume that the anterior part of the joint is most likely affected; and when the abscess is extra-pelvic in origin, that the posterior portion is probably the seat of deepest involvement. Since we desire, especially in females, to do as little damage as possible to the healthy part of the joint, the problem is presented of reaching the disease, as far as may be, through comparatively unimportant soft structures. I propose two distinct procedures, according to these indications. The method of reaching the lesion when the abscess is *extra-pelvic*, is that practiced in the cases operated upon by Sayre, Tiling and Gant, namely, by simple incision over the joint, and *évidement* with the usual instruments. The operation may be performed systematically, as I have demonstrated repeatedly on the cadaver. A straight skin incision should be made from the lower border of the posterior superior spinous process of the ilium downward, that is, parallel to the spines of the sacrum, for a distance, in the adult, of about two and a half inches. If a sinus exist it should be enlarged with the sharp spoon, and if sufficient space is thus gained the operation may be completed without removing any bone except that which is diseased. If more space is needed it should be obtained by sub-periosteally removing, with a small chisel, a portion or all of the posterior inferior iliac spine, since access to the deeper part of the joint is more readily obtained by this process than by removal of part of the sacrum.

But when only *intra-pelvic* abscesses have formed, and we have reason to believe that the disease process lies chiefly in the anterior part of the joint, we must have recourse to the *second* procedure referred to, by which, if possible, the the posterior and sound part of the joint need not be disturbed. Now it must be remembered that the longitudinal axes of the auricular surfaces of the sacrum and ilium are directed antero-posteriorly, that is, almost perpendicularly to the flat surface of skin overlying the sacrum. Hence the broad expansion of the joint surfaces lies at a depth, in the adult, of two and a half to three inches from the surface. This surface may be reached as follows: The patient lying on the unaffected side with the thighs in exaggerated flexion, a longitudinal incision exposes the posterior *superior* spinous process of the ilium, from

which the periosteum and tendonous attachments of muscles are removed by dull instruments. With a pretty large chisel a piece of bone is now cut away from the iliac spine so as to allow the passage of the finger into the pelvis major, the inter-osseous ligaments having been divided by the knife. The anterior borders of the articulating surfaces are thus exposed to the touch of the surgeon, who, with the aid of a Volkmann's spoon with a long curved handle, can easily reach tubercular matter both in the bones and in the soft parts. Iodoform gauze acts as a sufficient drain.

This systematic operation was suggested by an operation done by myself, under the direction of Dr. Chr. Fenger, of Chicago. A man 32 years of age presented a "cold abscess" in the right iliac fossa, and another larger one between the crest of the ilium and the twelfth rib. For a number of reasons a diagnosis had not been made prior to the operation. The lumbar abscess having been freely opened and its walls scraped, a fistula was found by means of a probe leading downward and forward, in front of the posterior superior iliac spine into the pelvis, where denuded bone was felt. The chisel was used to remove a portion of the posterior superior spinous process of the ilium; the finger was then introduced into the larger pelvis, and the tubercular focus being located in the sacro-iliac joint, and exposed to the touch, no difficulty was experienced in removing it. The iliac abscess was drained and complete recovery ensued.

The points in treatment submitted to your further consideration are as follows:

1. *Where no abscesses have formed*, hygienic and general symptomatic treatment, with counter-irritation by means of the thermo-cautery where pain exists or improvement is slow, should be combined with complete mechanical rest, aided by extension.

2. *Where abscesses or their resulting fistule exist*, cases should be subjected at the earliest practicable moment to a thoroughly radical operation by *évidement* performed posteriorly, that is, directly, when the abscess is extra-pelvic in origin; performed, as it were, from the pelvic side, whenever the abscess originates within the pelvis.

CHOREA OF THE SOFT PALATE.

CAUSED BY THE HYPERTROPHY AND HYPERÆSTHESIA OF THE MUCOUS MEMBRANE COVERING BOTH INFERIOR TURBINATED BODIES.

Read before the American Rhinological Association, at Cincinnati, Ohio, Sept. 12, 1888.

BY J. E. SCHADLE, M.D.,
OF ST. PAUL, MINN.

That the origin of not a few reflex nervous disorders can with a certain degree of exactness be traced to the presence of morbid conditions of the naso-pharyngeal cavities, is a question no longer

doubted. The observations of recent writers on rhinological subjects furnish us conclusive evidences that some forms of headache and of spasmodic asthma are in many instances the outgrowth of a nasal polypus, a turbinated thickening, or a septal deformity. The fact, too, is known that these reflex neurotic disturbances disappear soon after appropriate measures of treatment have been directed towards the removal of their cause.

The purpose of this paper is to call the attention of the Fellows of this Association to a case of choreiform movements of the soft palate appearing in a young lady whose family history is somewhat unusual, as well as remarkable, and whose affliction is without doubt phenomenal. The patient was referred to me by my friend, Dr. Baker, of this city, whose letter of introduction reads as follows:

"ST. PAUL, Minn., April, 16, 1888.

"*Dear Doctor*.—This interesting case came under my care June 3, 1887. The only thing complained of was a constant contraction and relaxation of the levatores palati. Each contraction carried the uvula upward and backward till it came in contact momentarily with the upper and back part of the pharynx. The relaxation and separation of the moist mucous membrane surfaces caused the sound. The noise was like that produced by a rapidly ticking watch, and of the same frequency. It was never absent except during sleep. The young lady was in excellent health, all the bodily functions being well performed. My treatment was as follows:

R. Zinci bromidi ʒj.
Syr. simplicis ʒj.
℞ Sig. Ten drops in water four times a day, increase one drop each day until the dose nauseated.

"This not producing the desired result, I gave tr. physostigmatis in doses ranging from fifteen to thirty drops. After continuing this remedy for a time, I abandoned it and prescribed fl. ext. cimicifugæ rac., in doses of fʒss to fʒj, every four hours.

"About July 7, 1887, I began the trial of galvanism, used eight cells of McIntosh battery and placed the positive pole with a sponge electrode at the back of the neck; the negative pole with a metal-tipped electrode such as is used for the urethra, was applied to the palate just above the uvula. The sittings were of five to ten minutes' duration, and I increased the number of cells to eleven. At the second treatment movements ceased and did not return for several hours.

"After the fifth or sixth application the ticking stopped and did not return till the first of this month when she called on me. Examination showed enlarged tonsils, with evidences of throat and nose disease. Thinking the condition of the nose and throat caused a return of the choreic movements, and cure of same might permanently relieve, I now introduce her to you for examina-

tion and treatment. A singular feature of the case is that her general health had been almost perfect through all these years. Another item of note is that no other sets of muscles were involved.

Yours, truly,

J. F. BAKER."

In the *Archives of Otolaryngology*, Vol. xii, No. 1, March, 1883, this same case is reported by Dr. Cornelius Williams, a distinguished oculist and aurist of this city. In this article Dr. Williams says: "When Violetta was ten years old, having occasion to get up in the night, she lost her way in going back to her bed, and reaching her grandmother's room by mistake she laid her hands upon the aged lady in the dark, and so alarmed her, and was herself so much frightened by the grandmother's shrieks, that she almost went into convulsions. She refused to return to her own bed, but lay in her sister's arms, starting and sobbing, the night through. Next day she was extremely pale and nervous, nor did she recover her wonted spirits for a number of days. This happened in the Spring of 1880, and a short time after this the child discovered that a strange clicking sound was produced in her mouth, but suffering no inconvenience from it she mentioned it to no one.

"In the June following she fell into Lake Elmo (Minn.), and came near being drowned, and a short time after this she called the attention of her mother to the clicking, which had now become constant. The family medical attendant was consulted, who pronounced it as a common affair. The uvula was cut off entirely, and one tonsil was amputated without result as far as concerned the clicking. The patient is in good general health; appetite and digestion good; sleeps well. She is easily fatigued, but is kept up by any excitement. There has been for the last three weeks diurnal incontinence of urine, the act of micturition recurring about every half hour, but at night it is hardly ever necessary for her to get up more than twice. Dr. D. W. Hand, who was kind enough to examine her, informs me that there is considerable leucorrhœa, and that the urethra is unusually large and patulous. He explored the bladder and found no evidence of stone. The act of micturition is not painful. Drs. Hand, Boardman, Abbott, and Wheaton, examined her heart at my request, and report that there is nothing abnormal about it. Upon looking into the patient's mouth it is perceived that the velum palati is rapidly raised and lowered without being made tense in its entirety. At the moment of relaxation of the levatores a sound is produced which is as much as can be like the ticking of a small brass clock, and in a still room it may be heard at a distance of twenty feet. The clicking corresponds to a complete contraction and relaxation of the levatores palati, and by actual count is 120 a minute, with very little variation in frequency at any time. When the mouth is opened widely the azygos

uvulæ is sometimes seen to contract, but such contraction would seem to be physiological.

"The tone of the clicking is changed by closing the nose, and by otherwise altering the usual conditions of the mouth and nose as to the volume of air contained, but that, nor any other manipulation, procures the cessation of the noise or its cause. Laryngoscopic examination shows the larynx to be normal, save a slight congestion. Rhinoscopy is not practicable. Otoscopy reveals the membrana tympani of each ear slightly indrawn, the handle and short process of the malleus of the right being abnormally prominent. Light spot gone from both Mtt.

"By means of the 'diagnostic tube' I am able to hear the clicking sound in either of the patient's ears; more distinctly in the right. It may very well be likened to the ticking of a watch under a pillow, or the sound of the foetal heart. If there is any movement of the membrana tympani, I have not been so fortunate as to observe it. The girl's voice is natural, and she can sing with correctness, uttering the chest notes without difficulty, but is unable to produce head notes at all. In running the scale, a decided tremolo is remarked. The patient, of necessity, breathes through the mouth, and from habit keeps it open during sleep. When there is tonsillitis, to which she is subject, there is considerable drooling. At such times she is apt to have glottic spasm. The spasm of the levatores ceases during sleep. At irregular intervals, perhaps fifty or a hundred times through the day, there is an interrupted spasm of the diaphragm, giving rise to a sudden and deep inspiration in two or three motions, as in sobbing, followed by prolonged expiration. At times, it may be for an hour or half a day, she hears in her ears a sound comparable to the rapid revolution of a small fan-wheel. Acuteness of hearing normal."

With the above information relating to the previous history, we are brought to the present consideration of this singular malady, a condition which I prefer to speak of as choreiform movements of the soft palate.

In company with her mother, Miss V. Z. presented herself at my office for examination on the 16th of April, 1888. She is a decided brunette, 17 years of age. General appearance is good; tall and well developed. Seems to be of a cheerful temperament.

Menstruation commenced normally, the epochs occurring regularly up to the present time. Digestive organs in a fair condition; suffers from constipation and flatulency quite frequently. Urinary function normal. Heart's action more or less excited; the heart beats tumultuously when ascending a flight of stairs, a hill or some other elevation. Complains in a marked degree of obstructed nose-breathing; dry sensation of the pharynx, disturbed sleep, and incessant mouth-

breathing. Organization is of the nervous type; excitement affecting nervous system is not well borne. Voice is impaired, especially when attempting to produce head tones, as in singing. The principal affection complained of, and for which she was referred to me, is the spasmodic movement of the velum palati.

Of the family history, particularly that part of it relating to the father's side, much can be said which not only has a special bearing on the case under consideration, but also gives valuable information for the neurologist. A predisposition to melancholia and suicide, handed down from the grandfather to the present generation, seems to exist. The grandfather, a Hungarian by birth, and a school-teacher by occupation, shot himself at the age of 58. An aunt, 55 years old, drowned herself in 1885. She was married, and was the mother of five children, one of whom, a son aged 28 years, came to his death two years ago by shooting himself. Another son, still living, suffered from melancholia for some time after the tragic deaths of mother and brother.

Conrad, father of Miss Z., at the age of 46, drowned himself while suffering from a fit of insanity. It is said he was an intelligent gentleman and an accomplished musician. In July this year, a brother aged 28 died from the effects of carbolic acid, which he drank with a view to self-destruction; this being his second attempt at suicide. The mother is healthy. Aside from an ancestral strumous tendency, her family history is good.

A faucial examination reveals distinct rhythmical choreiform movements of the velum palati accompanied by a peculiar clicking sound, distinctly audible for a distance of 12 or 15 feet from the patient. The levators of the palate seem to be the ones especially engaged in the production of these involuntary muscular phenomena. The levators act in unison with each other, and volition has no control over their behavior. The mucous membrane covering the palate and adjacent structures is anæmic, and has adhering to it a glistening tenacious secretion which, by ordinary attempts, is difficult to remove.

The left palatal tonsil is larger than it should be normally, a condition due to frequent attacks of acute tonsillitis to which she has been subject since childhood. Only a remnant of the uvula is to be seen.

By an anterior rhinoscopic examination I find chronic hypertrophy of the inferior turbinated bones, and in a more marked degree, of the middle ones, the presence of whose redundant tissue exerts pressure on the septum and produces obstruction. Posterior examination with the rhinoscope brings into view unusual chronic enlargement of the pharyngeal tonsil. It is lobular and irregular in shape, and extends with its free extremity from a broad base in the vault to some

distance below the upper margins of the choanae of the nose. Inspection of the posterior nares presents excessive chronic thickening of the pituitary membrane covering the posterior third of the inferior turbinated bones. That part of the nasal passages is almost occluded by this condition. The aspect of the septum posteriorly is thin and pale.

There is an important feature entering into the history of this case which must not be overlooked. I refer to the extremely hyperæsthetic state of the intra-nasal mucous membrane. Mackenzie's sensitive areas are prominently characterized by it. Even the margins of the nostrils sympathize in this respect with the mucous membrane lying beyond them. The presence of a speculum causes a disagreeable feeling and creates nervous irritation. The use of the probe in the chambers of the nose is utterly intolerable; contact of it with any portion of the membrane, and, more particularly with the posterior part of the inferior turbinated bones, at once gives rise to violent sneezing and spasmodic coughing. A flow of tears invariably follows these manipulations.

Treatment.—My treatment was mainly surgical. The first impression entertained was, that possibly the enlarged pharyngeal tonsil might have been a source of the trouble, and that a thorough removal of it would do away with a foreign element constantly coming in contact with the opposing surface of the velum palati, and exciting thus into action clonic spasms. Snaring was impracticable.

I therefore, by the use of Cohen's post-nasal cutting forceps, and of the electro-cautery, reduced the growth in its entirety. This procedure was ensued by cessation of the choreiform movements which remained absent for a period of two weeks, when they suddenly returned during a spell of nervous excitement from which the young lady was suffering.

My attention was now turned to the treatment of the nasal passages. The pathological changes found in them offered a theory for a reflex cause of the affection. Cocainizing the intra-nasal mucous membrane generally produced relief for half an hour. With a view to reduce the hyperæsthesia and hypertrophy of the turbinated bodies, I employed the electro-cautery, thoroughly burning the affected parts. An immediate result took place; the trouble at once ceased. Two cauterizations were necessary to effect entire perviousness of the nostrils and overcome obstructed respiration of the nose. Nose-breathing displaced mouth-breathing, and the dry sensation and sticky secretions of the pharynx gradually disappeared. The patient soon showed improvement in other respects.

The functional derangement of the heart and shortness of breath passed off, while the general

nervous system also gained tone. She also can now speak and sing with a clearer voice, the head tones improving daily.

Beyond a doubt a cure has been produced, the permanency of which already having been severely tested.

The melancholly death of her brother by suicide, mentioned in the family history, having occurred in the meantime, in itself was sufficient to reproduce the disturbance in consequence of intense emotional excitement into which she was thrown at the time. Upon receiving the news she was immediately seized by a violent attack of hysterical laughing which continued uninterruptedly for at least an hour. From this condition she passed for a few minutes into general muscular twitching. The velum palati, however, remained then as well as until now perfectly quiescent.

Etiology.—The choreiform movements of the soft palate as they were seen in this case, doubtlessly had for their origin a reflex cause, situated in a neoplastic and hyperæsthetic condition of the intra-nasal mucous membrane. In view of the fact that another exciting element has been mentioned as figuring in the etiology of the affection, the nasal disease may be termed the remote exciting cause.

Reference to a quotation from Dr. Williams informs us that the peculiar disorder of the velum palati became apparent soon after the patient, when still a child, had experienced on two consecutive occasions severe fright. This he maintains developed by its immediate exciting influence, the movements, which occurrence, it is my belief, simply brought into conspicuous activity what the reflex cause years before already had established.

The family history unmistakably illustrates a neurotic diathesis which evidently forms the predisposing cause.

Dr. C. E. Riggs, of this city, Professor of Nervous and Mental Diseases in the Medical Department of the University of Minnesota, who at one time saw the patient, personally related to me the following opinion when speaking of the nervous origin of the trouble:

"The antecedents and personal history of Miss Z., as related to me, clearly indicate the unstable and illy balanced condition which characterizes the nervous diathesis.

"Following the teaching of Pierret, we may regard all the intracranial nerves as analogous to a spinal nerve: the posterior root of this hypothetical nerve being the sensory portion of the fifth, its anterior root all the intracranial motor nerves, including the motor portion of the fifth. This hypothesis readily explains the clonic spasm of the levator muscles.

"Catarrhal states of the mucous membrane, more especially of the nasal and pharyngeal pass-

ages, may have their origin in a poorly nourished nervous system.

"The facial nerve gives off in the aqueductus fallopian three branches, two of which, the great and small superficial petrosal nerves, furnish motor influence to the levator palati, the azygos uvulæ, the tensor palati and tensor tympani muscles; through Meckel's ganglion the great superficial petrosal nerve is distributed to the levatores palati.

"The diseased surfaces under consideration derive their sensation from the fifth. The catarrhal condition of these mucous surfaces may be considered both as a cause and an effect, but the prime factor in the evolution of this peculiar clonic spasm I believe to be the intense nerve sensitiveness of the patient, since, without it, there would have been no reflex excitation, but a purely local condition.

"The excessive hyperæsthesia of the diseased tract clearly shows great irritation of the terminal sensory filaments of the fifth nerve.

"Accepting Pierret's hypothesis that the cranial nerves, as a whole, comport themselves like a spinal nerve, the reflex nature of the spasm is readily describable."

That this is a rare case is quite evident; whether another just like it has as yet been reported is doubtful.

The cases reported by Sajous (*Universal Annual*), and by Burnett (*Trans. of the American Otological Society*, vol. iii, part 3), were, it appears, particularly associated with disease of the Eustachian tubes or ears, and the crackling noises characterizing them the authors ascribe to aural complications.

Mackenzie, in Wood's "Reference Handbook," when speaking of the subject, says: "Clonic spasms of the soft palate, with objective noises in the ear, dependent upon neuralgia of the trigeminus, have been observed by Scheck."

A series of interrogations always gave negative results in the case I have here reported; no information could be obtained which led to the belief that Eustachian or aural diseases had at any time existed.

Then, as to the clicking sound; what produced it? It was seen distinctly that the levator muscles of the palate were the only ones engaged in the spasmodic actions; therefore, by repeatedly watching these phenomenal movements, the conclusion seems reasonable that the click resulted from the combined effect of muscular rigidity and sudden disengagement of the velum palati from the pharyngeal vault.

104 East Third St.

A SOCIETY of German Dermatologists is to be formed. Circulars have been sent out by Professors Neisser and Pick, and a committee has been formed for carrying out the plan.

MEDICAL PROGRESS.

ANALYSIS OF 500 CASES OF ACUTE RHEUMATISM.—DR. H. WALTER SYERS thus analyzes 500 consecutive cases of acute rheumatism:

Every case of acute rheumatism admitted to the Westminster Hospital during the last seven years has been carefully investigated with especial reference to the inheritance of rheumatism, nervous disease, and of phthisis. Attention has also been given to the subject of heart lesion. The analysis given below is based upon an examination of 500 consecutive cases, the history having been obtained for the first four years by Mr. Hebbert, medical registrar during that period, and continued by myself.

Sex.—There were 235 males and 265 females.

Age.—Under 5 years, 1; from 5 to 10, 26; 10 to 20, 188; 20 to 30, 154; 30 to 40, 90; 40 to 50, 29; 50 to 60, 10; over 60, 2.

Inheritance.—(a) There was a history of *rheumatism* in near relatives of the patient (father, mother, brother, sister, uncle, aunt) in 193 cases, or in 38.6 per cent. of the whole number admitted. A history of acute rheumatism in members of the family similarly related to the patient was found in 107 cases, or in 21.54 per cent. of the whole number. A history of acute rheumatism occurring in either parent was found in 46 cases, or in 9.2 per cent. of the whole. I have further ascertained the number of cases with acute rheumatism inheritance occurring at each period, and have compared these numbers with the numbers representing the cases occurring at the corresponding periods. The result is as follows:

Age.	Total.	Acute Rheumatism Inheritance.
Under 5	1	1
5 to 10	26	7 1 in 17
10 to 20	188	62 1 in 3.03
20 to 30	154	24 1 in 6.4
30 to 40	90	0 1 in 10
40 to 50	29	3 1 in 9.6
50 to 60	10	1 1 in 10
OVER 60	2	0

(b) *Gout.*—A family history of gout was obtained in only 38 cases, 7.6 per cent. of the whole number.

(c) *Neurosis.*—Of nervous disease in the family history I found 80 cases or 16 per cent. Of these 80 cases, a family history of insanity was obtained in 39 cases, and a history of epilepsy in 22 cases.

(d) *Phthisis.*—In 83 cases (16.6 per cent. of the whole number) there was a family history of phthisis found. Thus the percentage of cases owing a phthisical family history is a fraction greater than that representing a neurotic inheritance.

Heart.—The cases complicated with heart affection were 267, or 53.4 per cent. of the whole. Of these, there were 48 cases (17.9 per cent.) of

pericarditis, 83 (31 per cent.) of endocarditis, and 136 cases (50.9 per cent.) of combined endocarditis and pericarditis. In 160 cases it was possible to ascertain the age at which the heart affection occurred, and the result is as follows: Under 5 years of age, 0; 5 to 10, 14; 10 to 20, 87; 20 to 30, 37; 30 to 40, 16; 40 to 50, 4; 50 to 60, 2; over 60, 0. The percentages of the numbers admitted with heart affection (for the first time) at the corresponding ages being as follows: Under 5 years of age, 0; 5 to 10, 51.85; 10 to 20, 46.52; 20 to 30, 24.02; 30 to 40, 17.7; 40 to 50, 13.8; 50 to 60, 20; over 60, 0.

Only in 19 cases was the occurrence of *chorea* noted in the history of the patient, either before admission, during the attack of acute rheumatism, or during convalescence. Of these 19 cases, 12 were females and 7 males. In 7 cases the chorea was followed by acute rheumatism; in 4 cases the attack of chorea occurred during convalescence; in the remaining 8 cases the chorea and the rheumatism were separated by an interval varying from several months to several years.

Season.—From January to March, 146 cases were admitted, or 29.2 per cent.; from April to June, 92 cases, or 18.4 per cent.; from July to September, 120 cases, or 24 per cent.; and from October to December, 142 cases, or 28.4 per cent.

From April to September, 205 cases, or 41 per cent., were admitted; from October to March, 295, or 59 per cent. In January were admitted 54 cases; in February, 48; March, 44; April, 32; May, 28; June, 32; July, 28; August, 45; September, 47; October, 56; November, 34; December, 52; total, 500.

Mortality.—The total number of deaths was 15, or 3 per cent. Of males 9 died, and 6 females. There were 2 deaths with hyperpyrexia, the temperatures attained being respectively 108.8° and 107.2°; 1 death resulted from ulcerative endocarditis, 5 from pericarditis and endocarditis, 1 from pericarditis and pneumonia, 1 from pneumonia, 2 from collapse, and 3 from old-standing morbus cordis.—*Lancet*, June 30, 1888.

TREATMENT OF UNUNITED FRACTURE OF THE NECK OF THE FEMUR.—In the *Riforma Medica*, of August 14, a case is related, in which PROF. LORETA successfully treated an ununited intra-capsular fracture of the neck of the femur, by scraping the fractured surfaces and inserting a bundle of metallic sutures between them. On January 23, a robust man, æt. 36, was admitted into the Bologna clinic with the history of a fall on the left hip, nineteen months previously, since which he had been quite unable to stand, and had suffered from constant severe pain, shooting from the left hip-joint into the gluteal region, the point of greatest intensity being over the course of the

sciatic nerve. The limb was much wasted, but it was normal in position, and scarcely at all shortened. Flexion and extension of the thigh on the pelvis were almost impossible, but the patient could occasionally execute very slight movements of rotation and abduction. In rotation, he was sometimes conscious of faint crepitus in the trochanteric region. Feb. 15, Prof. Loreta operated with full antiseptic precautions. He made a long incision behind the great trochanter to expose the capsule of the joint, when he noticed a depression between the intra-capsular and extra-capsular portions of the neck of the femur. On moving the limb, it was found that there was a fracture without displacement in that situation. The capsule was then opened, the fibrous tissue between the fragments divided, and the fractured ends carefully freshened by scraping with a raspator. As it would have been very difficult to wire the fragments, a bundle of from eight to twelve metallic sutures was introduced between them, and brought out at the lower angle of the external wound. The wound was carefully cleansed, a drainage-tube inserted, the edges brought together with deep and superficial interrupted sutures, and the whole covered with a sublimate dressing. A long outside splint was then applied. Five days after the operation, the bundle of metallic sutures was removed, and the wound healed by first intention. In less than a month the pain had permanently ceased, and fifty-five days after the operation the patient left the hospital, being able, not only to stand, but to walk with no further support than an attendant's hand.—*British Medical Journal*, Aug. 25, 1888.

THE USE OF SALOL IN THE DISEASES OF CHILDHOOD.—DEMME has used salol in four cases of acute articular rheumatism, in two of acute endo- and pericarditis accompanied with articular fluxion to a moderate degree, and in two of catarrh of the bladder; also a topical application in two cases of burns. In the first two patients with the acute rheumatic polyarthritides, two boys of 8 and 13 years of age, the salol was given as long as the febrile symptoms persisted, as well as the swelling and redness of the joints, in doses of 3 or 4 grams daily. This dosage was continued with the first for five and the second for seven days, the dose being reduced to 2 grams and then to 1 gram during convalescence. In the third case, a girl of 7 years, in which all the articulations were swollen, and the fever was considerable, 20-grain doses of salol were given, and in forty-eight hours the intensity of the process had greatly diminished. The fourth patient was a girl 9 years of age, who vomited the first dose of salol which was given. An enema, containing 2 grams of salol, was then given, but in eight or ten hours an urticaria appeared which involved the entire surface of the body. The

salol was suspended, and two days later a dose of salicylate of soda produced an eruption similar to that produced by the salol.

Antipyrin was then given in gram doses, and in five days the rheumatism disappeared. In the two cases of endo- and pericarditis salol produced a favorable effect only when the cardiac action and intravascular pressure had been regulated by digitalis. The first of the two cases of catarrh of the bladder was caused by cantharides in a boy 5 years of age. The salol was given in doses of 1 gram, and this was gradually increased to 2½ grams; after two days the urine became acid, more abundant, and caused less pain in its passage. The case was cured in fifteen days. The second case was chronic cystitis following measles, and was equally well treated with salol. In the two cases of extensive burns the salol was mixed with an equal quantity of talc powder and dusted upon the wounds, which quickly cicatrized.—*Archives of Pediatrics*, September, 1888.

TREATMENT OF DIPHTHERIA.—COUSOT discusses anew the question whether diphtheria is primarily a general disease with local manifestations, or whether the diphtheritic membrane is the first factor in a general intoxication. The author believes that the great point is to combat the local manifestations from the beginning, and that they constitute the origin of all subsequent accidents. He believes that the following principles should dominate all rational treatment of this disease:

1. The medical treatment of diphtheria should be principally local at the beginning of the disease.
2. The organized germs of the products of diphtheria should be destroyed or sterilized wherever they occur.
3. Putrefaction of the elements of the diphtheritic membrane should be prevented at all hazards.
4. If the disease has reached an advanced period and general poisoning has supervened, local treatment should still be rigorously continued, in addition to the adoption of suitable means for controlling the general symptoms. The best means for the treatment of diphtheritic products with which the author is acquainted is a preparation of tannin, alcohol and mucilage applied with a syringe. Tannin is a safe antiseptic which may be extensively used without fear of injury to delicate tissues. The mixture which the author uses contains:

Mucilage	100 parts.
Tannin	10 "
Alcohol	2 to 20 "

If the false membrane is discovered when there is only a single patch upon the skin or the mucous membrane external to the air-passages, applications of the tannin may prevent its spread. If the pharynx, tonsils, or nasal fossæ are involved, the mixture should be injected by the mouth or nose every two hours. Evidences of putrefaction

will disappear after the first few injections, the membranes will shrivel, and the underlying mucous surface will assume a healthy red appearance.—*New York Medical Journal*, Sept. 15, 1888.

TREATMENT OF RUPTURE OF THE BLADDER.—In an original memoir contributed to the July number of the *Archives Générales de Médecine*, DR. A. BLUM has reported a case under his own care of intraperitoneal rupture of the bladder with peritonitis successfully treated, after an interval of forty hours, by laparotomy and suture of the wound. Of twelve recent cases—eleven collected from English and German sources—in which laparotomy was performed for intraperitoneal rupture, six ended in recovery and six in death. In the table of collected cases published by Bartels in 1878, ninety-three out of ninety-four cases were fatal. The following conclusions are given by Dr. Blum at the end of his paper: "The surgeon, in dealing with a case of certain or supposed rupture of the bladder, ought not to hesitate to incise the linea alba as soon as possible, in order that he may make out precisely the seat and extent of the lesion. If the laceration is seated near the base of the bladder—that is to say, if the peritoneum be not involved, perineal cystotomy will be indicated. In cases of intraperitoneal rupture the edges of the wound in the bladder should be brought together by sutures, and the 'toilette' of the peritoneum be performed without subsequent drainage. The best kind of suture, and the only one that has been successful in man, is that of Lembert (sero-muscular suture, not including the mucous membrane). When, in consequence of its situation and extent, the wound cannot be united, it should be sutured, if possible, to the abdominal wound, or drainage should be effected, according to the practice of Socin, by an artificial perineal wound. The existence of peritonitis at the time of operation is not a contraindication to stitching of the wound in the bladder. Still, the earlier the performance of laparotomy the better are the chances of success.—*London Medical Recorder*, August 20, 1888.

THE RESECTION OF GREAT VENOUS TRUNKS IN THE EXTIRPATION OF MALIGNANT TUMORS.—MADELUNG has been trying the effect of resecting the great venous trunks near malignant tumors when the cancerous disease did not appear to have become generalized, on the ground that the veins with the lymphatics form the road by which cancer extends. Schevan, in his inaugural thesis (*Contrib. f. Chir.*) reports fifteen cases. In eleven the jugular was resected, once on both sides. Twice there was resection of the common carotid and of the jugular at the same time, eight times for glandular metastatic carcinoma, and three times for lympho-sarcoma. In four other cases the femoral vein was resected, once with resection

of the artery, twice for cancerous glands following primary disease of the genitals, once for a tumor of the vagina, and once for primary cancer of the glands. Three patients died as a result of the operation; one of gangrene of the lower extremity and septicæmia following resection of the femoral vein, another as a result of resection of the common carotid and jugular, a third without the cause of death being positively established. Three died of local return, two of exhaustion, and two more of the primary disease, which could not be removed. Two were still alive, though suffering from a fatal return of the disease, and one was cured, though the observation dated only one month after the operation. Two patients were considered as cured; in one, death followed two years after the operation without any return, and the other had lived three years without a return.—*New York Medical Journal*, Oct. 6, 1888.

RESECTION IN ARTHRITIS DEFORMANS.—ZESAS, of Bern, in a paper on this subject, discusses the results of resection in cases of arthritis deformans with regard to the relief of pain, freedom from relapse, and the functional capacity of the limb. There seems to be good reason for asserting that the pains which cause so much distress in coitis deformans will be removed after resection, and reference is made by Zesas to permanent and complete relief of pain after resection of the elbow-joint for arthritis deformans. The results of the resection of the hip performed by Dr. Niehaus two years and a half ago, and those of like operation on other joints affected with arthritis deformans, show that there is no tendency to a recurrence of this disease after such treatment. With regard to the functional results of the operation, on the other hand, the prognosis is very unsatisfactory, since in three of the cases of resection of the hip in which reports have been given of the subsequent condition of the patients, the limb was too weak to sustain the weight of the body, and locomotion could not be effected without the use of crutches or some other means of support. It remains for subsequent and more abundant experience to determine whether such unfavorable results be due to the advanced age of the subjects of coitis deformans or to the nature of the affection itself, which may possibly prevent the development of a serviceable joint.—*Deutsche Zeitschrift für Chirurgie*, Bd. 27, Hft. 5 and 6.

A SUBSTITUTE FOR COD-LIVER OIL.—LAMANDE recommends the following as a substitute for cod-liver oil:

Glycerine	5x.
Tincture of iodine	5ss.
Iodide of potash	grs. xij.
m	

S. One teaspoonful fifteen minutes before meals.

SATURDAY, OCTOBER 20, 1888.

THE BRADSHAWE LECTURE ON URÆMIA.

The Bradshawe Lecture before the Royal College of Physicians this year, by DR. WILLIAM CARTER, was on a subject of great interest, which was ably handled by the lecturer. Beginning with the definition, "Uræmia may be defined as the altered condition of health caused by the accumulation within the body of poisonous products that should be eliminated by the kidneys," the lecturer points out that the symptoms of this altered condition are so various in themselves, and so variously combined, that within the limits of this general definition what on the surface appear to be altogether different diseases are formed; and it is not surprising that many explanations have been offered of such varying phenomena.

After a careful review of Traube's theory of uræmia, that the nervous symptoms are due to cerebral anæmia, and never occur without preceding cardiac hypertrophy and blood-dilution; that heightened blood-pressure causes cerebral anæmia, and as this affects one or another portion of the brain, there will be a preponderance of either coma or convulsions, the last being limited if the anæmia is limited, general if it is general, Dr. Carter is not inclined to support this theory. Much good work in renal pathology has been done by the French School of late years, and this is specially considered and discussed by Dr. Carter. The modification of Traube's theory adopted

by Jaccoud and by some eminent English clinicians seems far from unreasonable to him. It will be remembered that Traube's theory was called forth chiefly by the fact that the brain is pale and watery in some cases of death from uræmia. This, however, is not a constant pathological condition. Nevertheless, this condition should be regarded as of considerable importance, and may not, after all, be so antagonistic to the views of the chemical pathologists as they think. "We have," says Dr. Carter, "no absolutely certain *post-mortem* signs that enable us to say that either local dilatations or local spasms of cerebral vessels have occurred during life in any case of Bright's disease; but as, at any rate vascular spasm certainly occurs in other and sometimes strangely limited parts, where the death-like pallor which it produces can be plainly seen, it is at least not improbable that it may also occur in some of the vessels of the brain, where, from the nature of the case it cannot be seen."

But we must pass from this interesting aspect of the subject to the experimental methods of investigating uræmia. And we may begin by stating a cardinal point made by Dr. Carter, that uræmia is a toxæmia, and that whatever increases the flow of blood to the nerve-centres in a case of renal disease adds to the probability and danger of toxic manifestations. It is agreed that there is a poison producing the uræmia; but what it is we do not know. We may be said to know, however, that it is not urea, not carbonate of ammonium, nor any one substance. We know that normal urine is toxic, that it contains alkaloidal and other poisons; if these be not properly eliminated the system must suffer from their poisonous effects. The experimental investigation of uræmia, while showing that the difficulties to be overcome are many and great before the pathogenesis of uræmic poisoning can be understood, show at the same time what some of the difficulties are, and give great encouragement. And while great caution is required in interpreting clinical facts by the results of experiments on the lower animals, yet the experimental investigations that have been made are gradually opening up new methods of practice, and at the same time show what was good in the older methods by giving reasons for their being good.

In his recent work on "Auto-Intoxication in Disease" Bouchard's conclusions in regard to

uræmia may be thus summarized: The urine as a whole is poisonous. The sources of its toxicity are fourfold—namely: 1. Aliments, especially their potassium compounds. 2. The absorbed products of intestinal putrefactions. 3. Secretions, such as the bile, saliva, etc. 4. Tissue disintegrations. These circulate in the blood, and, unless removed, poison the tissues. Bouchard showed experimentally that the nature of the toxicity of the urine varies according to many circumstances, and he has determined the presence of seven distinct toxic substances combined in the most variable proportions under different circumstances. Two of these substances were convulsant, one diuretic, one narcotic, one sialagogue, one pupil-contracting, and one temperature-reducing. We know, too, from recent investigations, that the urinary poisons have different effects according to the times and circumstances of their formation, at one time stimulating, at another inhibiting the same cortical cells of the brain, thus at one time causing paralysis and at another time convulsions in the animals into whose blood they are injected.

What then, in the way of treatment, have the experimental studies of uræmia taught us? Not only have these studies taught us newer and better methods of treatment, but they have pointed out earlier symptoms, the importance of the recognition of which cannot be overestimated. Dr. Carter shows that the principles on which practice must be based consist mainly (1) in cutting off one or another of the urinary poisons at their source, now that we know to some extent what these poisons consist of, and whence they are derived. Under this head we recognize the great importance (a) of limiting potassium salts both in food and in medicine, (b) of employing the simplest and most easily assimilated diet, such as milk, (c) of bowel disinfection, (d) of maintaining at its best the functional activity of the liver, (e) of care in the nature of nutrient enemata when these are required. (2) In directly and indirectly withdrawing or diluting the uræmic poison, by (a) venesection, (b) purging, (c) sweating, (d) transfusion. (3) By burning up the poison, by (a) active exercise, (b) the administration of oxygen or oxidizers. (4) In antagonizing the poison, or at least overcoming special symptoms. Practically, then, the sodium salts should be substituted for the potassium salts, the latter being forty

times as toxic as the former. The value of the milk diet has long been known, and the reason for its value is apparent. If it cannot be digested, then to the diet of foods that leave more residuum than milk must be added certain intestinal disinfectants, little soluble and non-poisonous, such as naphthalin, iodoform, and animal charcoal. As to the value of blood-letting in convulsions or coma, Dr. Carter thinks that if the pulse is hard and quick, a moderate bleeding will do no harm, even if the patient should be anæmic, and if he is not anæmic it will be likely to do good. Adding to the amount of blood, says Dr. Carter, will equally dilute the poison. Dieulafoy has cleared up the uræmic symptoms and secured great improvement by transfusing 120 grams of blood, and Dr. Carter has transfused freshly drawn goat's milk; or the solution of the chloride, phosphate and carbonate of sodium may be injected. The value of purgation and diaphoresis are so well known that they need not be insisted upon. Jaccoud's treatment of Bright's disease by inhalations of oxygen seems to promise good results.

For the relief of uræmic asthma, it is probable that most good will be obtained from the agents that relax vascular spasm, such as ozonic ether.

Dr. Carter's admirable lecture may be found in the *Lancet* of August 25, and in the *British Medical Journal* of September 1. One finishes reading it with the feeling that, obscure as the subject is, he knows more of it than he did before.

DISINFECTION AND DISINFECTANTS.

The first report of the Committee on Disinfectants of the American Public Health Association has just been issued. If there were no other *raison d'être* of the American Public Health Association, this volume alone would be sufficient. The Committee on disinfectants, it will be remembered, was composed of Drs. George M. Sternberg, Joseph H. Raymond, Charles Smart, Victor C. Vaughan A. R. Leeds, W. H. Watkins, and George H. Rohé.

The present volume contains the reports for the two years previous to 1887, which have already been noticed, and the report for 1887, which may in a certain way be regarded as an additional report with a summary of what is contained in the others. The report of the Chairman, Dr. Sternberg, is very full, as was to be expected. It is a

report of what he himself has done in the way of confirming the conclusions arrived at from work in former years. He discusses fully the data relating to the several disinfecting agents mentioned in the former reports. Former conclusions have been tested by experiments upon pure cultures of the various pathogenic and non-pathogenic bacteria available for this purpose. Elaborate and careful experiments have been made in regard to the thermal death-point of microorganisms, and conclusions drawn.

As to the single disinfectants, further experiments show that the high place at first given to chlorinated lime is fully justified; but Dr. Sternberg recommends that *Standard Solution No. 1* be made by adding 6 ounces of chloride of lime to the gallon of water, instead of 4 ounces. The results of the experiments of Dr. Meade Bolton, made for Dr. Sternberg, are in accord with those of Van Ermengern, and show that for disinfection of highly albuminous material the amount of mercuric chloride required will exceed that in the standard solutions (1:1500), formerly recommended by the Committee for sterilizing excreta. Preference is given to the chloride of lime solution for the disinfection of excreta. In regard to carbolic acid, a consideration of experimental data leads Dr. Sternberg to believe that carbolic acid possesses a decided advantage over mercuric chloride or over oxidizing disinfectants for the disinfection of masses of material to be left *in situ*, such as human excreta in privy vaults. This advantage is due to the fact that it is not decomposed nor neutralized by putrefying material, and that it will exercise its antiseptic action throughout the mass, even though it may not destroy spores or pathogenic organisms present. In the first report of the Committee sulphate of copper is recommended in a solution of 2 to 5 per cent. for the destruction of infectious material "*not containing spores*." Dr. Sternberg now says that this proportion may be reduced to 1 per cent., except in the presence of a considerable amount of albumen, when the amount must be increased. Pure calcium oxide is found to have no great value for disinfecting purposes, but as it has considerable germicide power when used in the form of lime wash, especially after prolonged contact, its general use for sanitary purposes is to be recommended wherever it can be applied to surfaces supposed to be infected by disease germs.

The most complete paper on Ptomaines that has appeared in the English language is the one contributed to this report by Dr. Victor C. Vaughan. Following this are two very valuable articles, "Methods of Practical Disinfection," by Dr. George H. Rohé, and "The Quarantine System of Louisiana—Methods of Disinfection Practiced," by Dr. Joseph Holt. These papers are well and profusely illustrated. The conclusions in regard to disinfection and disinfectants will be published, for the information of our readers, in another department.

This report may be obtained from Dr. Irving A. Watson, Concord, N. H.

AN UNSEEMLY QUARREL.

In plate V of Hogarth's "Harlot's Progress" is presented the spectacle of two disciples of Esculapius, who the commentator has the grace to insinuate are not regular, in a hot quarrel over a dying unfortunate, whom each charges the other with having poisoned. The scene points the moral that the doom is the pathetic rounding up of an evil career. Not a single character in this delineation shines with a reflected glory—all is dark, dismal and shuddering. There is a most woful want of all the proprieties, even down to the venal nurse despoiling a dilapidated trunk of its few valuables.

Now why should a magnanimous potentate, full of good-will to men, have been overtaken by the more cruel fate of a death made uneasy by domestic bickerings and court intrigues? Why should a noble profession, full of all beneficence, be besmirched by the quarrels of men oversensitive about a transitory glory, which might have been transferred by the will of the monarch upon the bragging professor of a cancer specific? Why should the "infallible" expounders of an art, who came to a diagnosis by the easy reading of a post-mortem backwards, have accentuated so-called snubs, while a desirable life was at stake?

"Not so happy—yet more happy," is the out-cast Lazarus in a Home for Incurables who is allowed to die in peace behind a friendly screen, with no public peering in at the windows and awaiting the flight of a wailing soul.

DR. PAUL GIBIER has been charged with a communication to study yellow fever in the United States, and particularly in Florida.

EDITORIAL NOTES.

ETHER IN HEART FAILURE.—PROFESSOR VON BAMBERGER has recently recorded, in the *Wiener klinische Wochenschrift*, an interesting case showing the effect of ether in cardiac insufficiency. The case was that of a man who came under treatment about two years ago, and who was suffering from cardiac insufficiency due to fatty degeneration (but no cardiac failure), and from considerable dropsy, albuminuria, hepatic enlargement, dyspnoea, and continual insomnia. The patient, a man æt. 60, was directed to try the Oertel "cure" in the mountains, but the dyspnoea and other symptoms became so aggravated before the "mountain cure" was begun, that the physician in attendance tried the effect of injections of ether. The effect of these injections was that the secretion of urine, which other drugs and means had failed to increase, rose to several thousand cc. daily, and continued so for some time; at the same time the dropsy and the dyspnoea decreased. The patient was now able to undergo the Oertel "cure," under which progress was made, but some months later he died of apoplexy. Bamberger thinks it probable that the good effect of the ether in this case was due to its action on the kidneys; though it may have acted as a direct stimulant to the enfeebled heart.

THE COLOSTRUM CORPUSCLE OF HUMAN MILK.—DR. EDGAR BECKIT TRUMAN, of Nottingham, has made some investigations to ascertain the significance of the colostrum corpuscle, and to ascertain the usual condition of the breast milk three months after confinement. Medico-legists usually mention the presence of colostrum in milk as characteristic of recent delivery. Dr. Truman, from a study of a number of cases, comes to the conclusion that the colostrum corpuscle is no proof of recent delivery, or of delivery, say, within the previous three months. It is a sign of incomplete development of the products of the mammary gland, and in this way we may get it with retroflexion of the uterus, prolapse of the ovary, incomplete action of the glands, chronic ovaritis, cancer of the breast, and dyspareunia with laceration, in all which cases we get the irritative action of disease, instead of the normal healthy activity of the reproductive organs. In fact, the presence of the

corpuscle would tend to negative the supposition of a delivery followed by three months' suckling. The record of Dr. Truman's cases may be found in the *Lancet* of September 1, 1888.

THE PHYSICIAN—A NATURALIST.—In THE JOURNAL of September 15, attention was called to the address before the recent annual meeting of the British Medical Association, on this subject, by Dr. Gairdner. In the *Edinburgh Medical Journal*, of September, is a graduation address on this subject by PROFESSOR SIR WILLIAM TURNER, delivered on August 1, just a week before Dr. Gairdner's address was delivered. Sir William's address is somewhat on the same lines as Dr. Gairdner's, and it is certainly a coincidence that the two should have been delivered at almost the same time. Sir William Turner calls attention to the value of complete and accurate observation, to the great value of the study of the sciences, and to the contemplation of Nature in disease, by which the physician becomes inspired with a desire to penetrate the mysteries of life and organization, and to remove the healing art from the domain of conjecture and hypothesis, and plant it on the firm ground of science.

INTUBATION TUBES; THE ALLEN SURGICAL PUMP.—We are pleased to observe the favorable notice our English brethren gave two Chicago devices exhibited at the recent meeting of the British Medical Association. They deserved the attention. Dr. Waxham's paper on "Intubation of the Larynx" was very favorably received, as all who know him would have prophesied. His modifications of the intubation tubes were exhibited, as well as the methods and results of intubation described.

Mr. Truax was invited to exhibit the Allen Surgical Pump by several members of the Association who saw it at the International Congress and who subsequently used it. We learn from the *British Medical Journal*, the *Lancet*, the *Asclepiad*, and other English journals that it excited much notice, as it deserved to do. It is so simple and its uses so manifold, and its cost so reasonable, that it deserves the popularity that it has acquired in this country and, as we hope, now in England.

THE PHONOGRAPH FOR RECORDING PULMONARY AND CARDIAC SOUNDS.—During his vacation the past summer, DR. WILLIAM PORTER,

of St. Louis, Mo., says he used some of his time in experimenting with the phonograph for permanently registering the fac simile of any abnormal sound produced in the lungs and the heart. (See *Weekly Medical Review*). He says: "Not only are different voice sounds presented distinctly, but by attaching the ordinary stethoscope some of the cardiac sounds could be easily recognized after they had been recorded by the instrument." The most perfect result he obtained was from a case of *mitral insufficiency*. The subject is worthy of much careful investigation.

REMOVAL OF SUPERFLUOUS HAIRS BY ELECTROLYSIS.—This operation, which is not difficult, though requiring some practice, does not seem to be perfectly understood. A writer in the *British Medical Journal* says: An irido-platinum needle is commonly used, and is inserted along the sheath of the hair until it reaches the level of the root. It is most convenient in practice to use a strength that requires about 30 to 35 seconds to loosen the hair sufficiently so that it comes out without traction when taken hold of by the forceps. In dealing with hairs on the upper lip or on the chin of women, it is advisable to operate only on hairs that are strong and black. So long as the hairs are colorless, unless they are very thick and strong, they are better let alone.

DR. ABNER HAGAR, of Marengo, Ill., died at his home September 22, 1888, aged 73 years, and 8 months. He was one of the early and highly respected practitioners of medicine in the northern part of Illinois. He graduated from the Medical College of Geneva, New York, in 1841, and in the same year commenced the practice of his profession, first in Dundee, Ill., then in McHenry, and in 1843 moved to Marengo, where he continued to do a large practice until within a few years of his death.

HORSE-FLESH is said to be regularly exposed for sale in the butchers' shops in Liverpool, and the authorities do not interfere so long as the meat is sound in quality and is offered as horse-flesh. A case recently came up in Liverpool in which ill-smelling horse-flesh was offered for sale, and a witness said he killed one or two horses every week; certainly a surprising statement when one thinks how few horses that are unfit for work are suitable for food.

DR. W. W. IRELAND, the author of "The Blot upon the Brain," will shortly issue a gallery of eccentric or insane persons who have had much influence upon men. The list will include among others Swedenborg, Louis Riel, Guiteau, Theodore of Abyssinia, King Theebaw, and Malagrida.

DR WM. OSLER, Professor of Clinical Medicine in the University of Pennsylvania, has been elected Professor of Medicine in the Johns Hopkins University and Physician to the Hospital, Baltimore, Md. A very excellent appointment.

THE FIRST NUMBER of the *University Magazine*, has made its appearance, and is filled with interesting papers. It is published monthly, in the interest of the Medical Department of the University of Pennsylvania.

SOCIETY PROCEEDINGS.

Philadelphia County Medical Society.

Stated Meeting, September 26, 1888.

THE PRESIDENT, J. SOLIS COHEN, M.D.,
IN THE CHAIR.

DR. SAMUEL W. GROSS read the following paper on

THE TREATMENT OF CARCINOMA OF THE BREAST.

Of operations which do not rank with major procedures, not one is more commonly practiced by men not skilled in the manual of surgery than that of the removal of the mammary gland for carcinoma. The superficial situation of the organ, the ease with which hæmorrhage is controlled, the flaps are united, and the dressings applied, all tend to make partial or complete extirpation of the breast a tempting field for the young surgeon. If to these considerations be added the great frequency of the disease, it will be seen that its treatment should constitute an instructive topic for consideration and discussion by this body.

In accepting your invitation, Mr. President, to make the opening remarks upon the subject, I take it that a brief narration of my own personal experience will prove to be more interesting than were I to deal with the practice of others, the more especially as the operation which I have performed is more thorough than the usual procedure.

At the outset I will state that in the manage-

ment of so lethal an affection I have relied upon the scalpel, as I believe it to be the one and only measure which is capable of affording good results. It may be that some of my hearers are sceptical as to the propriety of interference. The old tradition that carcinoma is an outward evidence of a blood disorder, and that it cannot, consequently, be cured by operation, may still influence a few of our members. To these I may be permitted to say, first, that the leading minds of the world now admit that carcinoma is primarily a local growth; and, secondly, as I have elsewhere¹ conclusively shown, from an impartial examination of a large number of cases that the knife not only prevents the local dissemination of the disease, its extension to the lymphatic glands, and the occurrence of secondary growths in a large percentage of cases, but that it moreover prolongs life, and definitely cures one patient out of every eight and a half.

An operation in a suitable case having been decided upon, the one selected by the majority of surgeons is that with which we are all so familiar, namely, the inclusion of the nipple and a portion of the skin in two elliptical incisions, the reflection of the flaps, and the dissection of the gland from the surrounding tissues. Other surgeons, actuated by the desire to save as much of the gland as possible, limit their efforts to the extirpation of the tumor alone. The first of these procedures is faulty enough; the latter cannot be condemned in too severe terms; and yet, in his recent monograph on "The Operative Surgery of Malignant Disease," Butlin, I am sorry to say, recommends it. A knowledge of the changes which, starting from the tumor itself, ensue in the remainder of the breast, in the adjacent soft tissues, and in the associated lymphatic glands, which changes indicate the local extension of the disease along the lymph paths, ought surely to lead the surgeon to reject such irrational operations. In very exceptional instances a cure may be effected; but we all know what is the common result—a more or less rapid recurrence of the disease—a favorable issue being so uncommon after these incomplete operations that few, if any, of us have ever witnessed it.

Dissatisfaction with my own earlier results and those which I was enabled to follow in the practice of other surgeons led me, ten years ago, to adopt a radical procedure, the object being to effect riddance of all the tissues in which the experience of hundreds of years demonstrates that recurrence, or a new outbreak of the disease, takes place. Hence, in my operation, which is minutely described in the *American Journal of the Medical Sciences* for April, 1888, I amputate, by a circular cut, the entire breast with its overlying skin and fat, dissect off the pectoral fascia, and carry an incision into the axilla, through which I am en-

abled to extirpate its contents. If nodules should be found in the pectoral or intercostal muscles, they are also removed with an equally unsparing hand. The edges of the wounds are then approximated, the closure of the breast incision being greatly facilitated by raising the flaps from the subjacent tissue for $1\frac{1}{2}$ to 2 inches, and the employment of button sutures. In some cases, the wound cannot be entirely united, so that it has to heal by the process of granulation.

In the discussion which will follow the reading of my paper, I will doubtless be asked, first, Why do you remove the entire breast and its surrounding tissues? and secondly, Why do you attack the axilla in all cases? My answer is, simply because recurrence, or a new outbreak of the disease, ensues in tissues which are left behind in the less radical modes of operating. The accumulated observations of surgeons show that recurrence may be anticipated in the skin and subcutaneous tissues, especially at or near the cicatrice; in the fascia covering the pectoral muscles; in the remnant of the breast from which the tumor alone was excised; in outlying lobules which were overlooked during the performance of the less complete operations, and in the lymphatic glands, particularly those of the axilla.

Answering these questions more fully, I would say that sound pathology, as well as experience, demands that the entire mammary gland, along with its circumjacent tissues, should be amputated, first, because we have to deal with a carcinomatous degeneration commencing at one point from which the cells migrate in various directions into the remainder of the breast and the surrounding tissues, the extent of which migration into the lymphatics and their radicles it is impossible to determine with the naked eye; secondly, because the disease is sometimes multiple, and the smaller growths are only detected on examining the breast after its removal; thirdly, because minute lobules frequently lie at some distance from the main body of the gland, particularly toward the axilla and the clavicle, which may subsequently become the seat of a new outbreak, even as late as ten years, as in a remarkable instance recorded by Banks; and fourthly, because nodules may be found in the subcutaneous tissues at a relatively great distance from the breast, which would certainly have escaped detection in the lesser operations.

My answer to the second question, Why do you attack the axilla in every case? is, because the axillary glands are almost always diseased, even though they cannot be felt prior to operation. Of my 45 cases, the glands were not palpable in 18, but in 15 of these they were present when the axillary space was opened. In 57 out of 65 similar cases, Kuester found that the glands were infected, so that our combined experience demonstrates that the glands are invaded in 86 out of every 100 cases in which there is no ex-

¹ *American Journal of the Medical Sciences* for April, 1888.

ternal evidence of their implication. Hence, if the axilla be not evacuated of its contents in every case, a subsequent operation will almost surely be demanded. In point of fact, I consider this step as the keynote of the procedure, and I refuse to operate if I am not permitted to have my own way in this regard.

Although the procedure which I have described may appear to be unnecessarily severe as to the sacrifice of tissue and, at first sight, seem to be attended with more risk than operations performed with a more sparing hand, I have still to present some facts which conclusively show that it is the best that has as yet been practiced as regards mortality, freedom from local recurrence, and a final cure.

Of my 45 cases, 2, or 4.44 per cent., perished from the operation, and 5 patients were lost sight of after recovery. Deducting the 7 that died and could not be traced, 38 cases show local recurrence in 11, or 28.95 per cent. Including the deaths, out of 40 cases, 9, or 22.5 per cent., recovered. Of these, 1 died of an intercurrent disease in 7 years and 10 months, while the remainder are still doing well, 1 for 9 years and 10 months, 1 for 9 years and 1 month, 1 for 6 years and 9 months, 1 for 4 years and 3 months, 1 for 3 years and 11 months, 2 for 3 years and 6 months, and 1 for 3 years and 5 days.

Let us contrast these results with those afforded by the next best operation, namely, the removal of the breast by flaps and the evacuation of the contents of the axilla in every case. Of 328 cases of this description in the hands of Banks, Kuester and von Bergmaun, 10.67 per cent. perished, there was local recurrence in 54.92 per cent., and 15.15 per cent. were cured, so that my operation is safer by 6.23 per cent., is less liable to local recurrence by 25.97 per cent., and affords 7.35 per cent. more of permanent recoveries.

It is quite certain that the greater immunity from local reproduction of the disease in my operation is due to the total amputation of the breast, its skin, and enveloping fat. Despite the fact that my results are better than any that have heretofore been recorded, a careful examination of the cases of Banks shows that he met with only 3.88 per cent. more of recurrences than I have, and that his percentage of recoveries, viz., 20.77, is only 1.73 per cent. less than my own. Hence, I felt that I might possibly have sacrificed too much of the skin; and, since June, 1887, I have so far modified my operation in 10 cases, the skin in none being apparently affected, as to save enough of that structure to admit of nice approximation of the edges of the wound. All recovered from the operation; one died from recurrence in the axilla and metastasis, one is living with axillary reproduction; in not one has there been local reproduction; one patient is free from disease at the end of fifteen months; one for one

year; one for nine months; and the remainder for periods varying between three and eight months. These cases can be followed, and whenever I am sure of being able to trace my patients, I shall give this procedure a fair trial. When, on the other hand, the patient lives at a great distance, or her circumstances are such as to prevent her visiting me in the event of recurrence, I will adhere to the more extensive operation.

DR. JAMES COLLINS: I have on two or three occasions, in the case of small tumors in comparatively young women, allowed myself to be over-ruled by the patient and her friends, who urged that it would be a pity to sacrifice so much of the breast as I proposed, to performing a restricted operation; but I have regretted it in every instance, and I can assure Prof. Gross that I will never offend again. That which Dr. Gross describes as the "second-best operation," the large elliptical incision with thorough removal of tissues beneath the skin and exploration of the axilla is the one I have practiced in the majority of my cases. The prolongation of life in those I have been able to follow would average not quite three years.

The great difficulty we have to contend with in mammary tumors is to secure consent to an early operation. Patients go from surgeon to surgeon, and from city to city, and finally yield consent as a last resort or in deference to an authoritative opinion; usually too late to escape recurrence. The recurrence which then takes place, despite skilful operation by a distinguished hand, will be cited in discouragement of timely operation in other cases, by a large circle of relatives and friends.

The exploration of the axilla, which the lecturer in his masterly demonstration has so justly emphasized, should never be omitted. Nor is it too trite a remark to recall that antiseptic methods, which have so improved the results of extended operations, should here also remove any lingering dread of opening up large spaces; for they have improved the outlook of the procedure by assisting the rapidity of healing, and excluding the danger of septic accidents and sequelæ.

DR. O. H. ALLIS: I have nothing to add in discussion; I have repeatedly seen Prof. Gross operate, and there is one point in his method of operation to which I would call especial attention. The breast having been covered for twenty-four hours with antiseptic solutions and his hands being thoroughly aseptic, he carefully palpates the pectoral region for outlying nodules, marking the site of any that he finds with a pencil-stroke, and when he operates he does not dissect out these places, but includes them well within the sweep of the line of incision. In other words, he cuts beyond the outer limits of the disease.

DR. JOHN B. ROBERTS: Dr. Gross has for

many years taught us all the proper way to remove a breast, that is, to remove it thoroughly. In my own operations, I have, whenever possible, employed the large elliptical incision; the advantage, and I confess the only one, being that when approximation of the edges of the wound is at all possible, it can by this method be more readily effected. No one who has learned from Prof. Gross the proper way to open the axilla would dare to neglect this portion of the operation. As to aseptic and antiseptic methods, there can be no difference of opinion among experienced operators; they are the only methods permissible in operative surgery. I would like to ask Dr. Gross how long it takes to repair one of the large spaces in what he calls the dinner-plate incision, and what his opinion would be as to the prospects of a plastic operation to aid in hastening healing.

DR. R. BRUCE BURNS: Of all surgical cases these are the most unsatisfactory. In my earliest operations I did not open the axilla. Three cases operated on in this way are living for eleven, nine, and five years respectively. Of later years I have opened the axilla, and have been unfortunate. Recurrence has taken place in the cicatrices and even in the axillary tissues, perhaps in small glands not removed. I have thought, perhaps, it recurred in the adipose tissues. I have usually employed the elliptical incision. The method of leaving a large open wound to heal by granulation is rather hazardous. In all cases where I have had to depend upon extensive granulation there has been rapid recurrence and metastasis. There may also be limitation of the movements of the arm from matting of the tissues. It is wise always to attempt to secure union by first intention. It would be well to attempt to remove outlying nodules in the surrounding tissues. Where nodules occupy a portion of the gland (mammary) and are intimately attached to it, the whole organ should be removed.

Antiseptic measures are only so far useful as, in arranging them, you secure aseptic conditions. I believe thorough cleanliness in all respects, as to instruments, dressings, and the surgeon's hands, with good drainage, is all that is necessary in the treatment of the wounds of operations.

DR. GROSS, in closing the discussion, said: There are many points which might have been touched upon in the paper which I omitted for the sake of brevity. Societies do not like to listen to long papers, and the best speakers teach little in long papers. The points I have tried to emphasize are, the importance of a thorough operation, and the fact that its results are better than those of incomplete operations.

Now as to primary union. Of course, I want to get primary union whenever I can. Those who have never seen my operation would be surprised to see how close an approximation we can

get by sliding the bistoury under the skin, say for from one to two inches, and then drawing the loosened flaps together with buttoned sutures.

Sometimes when there has been very extensive disease, necessitating correspondingly extensive operation, we have a gap left to granulate of two or three fingers' breadth—never more than three fingers' breadth. Healing may be slow in a debilitated subject with a large wound, but averages about six weeks.

Now as to saving the breast, and only removing the tumor itself—I do not care for the breast. It is of no use. I am concerned in getting rid of all diseased tissues. What surgeon would undertake to remove a sarcoma of the thigh, for example, and for the sake of leaving a little more stump, make his flaps through infiltrated tissue? I should consider such a procedure criminal. Yet it is just what some surgeons want us to do in the breast.

In my last ten cases I did, for reasons stated in the paper, the lesser operation, and if I find it equally satisfactory in the end, I will adopt it altogether. I am not wedded to one operation, only so far as not only personal experience, but the combined statistics of several operators with good results show that my operation has given the best results.

Dr. Burns has had an experience of coincidences. In the cases in which he did not open the axilla and recovery took place, he had a free axilla. I judge that the doctor thinks recurrence takes place in granulations. Now it is a histological fact that granulation tissue will give rise to granulation tissue alone, and not to epithelial tissue. The granulating surface may be great or small; that has nothing at all to do with recurrence. In those other cases all the disease was not removed, and hence development again took place in the tissues forming the bond of union, or the tissues near the cicatrice.

As to aseptic surgery, I can only say that if anyone has been taught the modern methods and neglects them, and death occurs from erysipelas, pyæmia or septic complication, he cannot be held irresponsible.

LETTER FROM PARIS.

(FROM OUR OWN CORRESPONDENT.)

Communication of the Amniotic Liquor and Maternal Blood—Clinical Urology of Small-pox—Relaxation of Ophthalmic and Dental Disorders—Time for administering Certain Drugs.

In a note in the *Archives de Tocology* on the communication of the amniotic liquid and the maternal blood Dr. Törngren remarks that the

former experiments of Gusserow, Fehling and Quinquaud had clearly established that soluble substances introduced into the circulation of the mother entered the ovum. Experiments were equally performed by Savory, Gusserow, Preyer and Bar in the opposite sense, to establish the passage in the "maternal" direction. But how the substances injected into the amniotic liquid returned in the maternal circulation was a point not very clearly elucidated, and it is this that Dr. Törngren endeavored to establish in his experimental work executed under the direction of Professor Strauss. He was able to establish, with Drs. Bar and Haidlen, that an absorption by the mother certainly took place of substances contained in the liquid of the amnios. As regards the channel followed for this absorption, the results are not absolutely decisive. Contrary to Schultze, Dr. Törngren, however, thinks that the absorption is not effected by the medium of the fetal organism (the child taking in in the first instance by deglutition the amniotic liquid), but principally by the placenta or the membranes. These experimental facts, observed in the rabbit, found their analogies in the anatomical researches made by Winkler on the placenta of the human female. He established that in the placental portion of the chorion and of the amnios canalicules exist which communicate with the amniotic cavity.

Dr. Robin has lately made a very interesting communication to the Academy of Medicine on the clinical urology of small-pox, a question which had never been treated in a systematic manner. The researches of Dr. Robin have led him to establish in small-pox four varieties of albuminuria: 1. Prevariolic albuminuria, occurring before the eruption. It is grave when it is abundant. Only one case of the kind has ever been known. 2. Transitory albuminuria. This is a little marked and shows itself at the outset of the eruption and of suppuration. It is of no diagnostic or prognostic value. 3. Abundant albuminuria, coming on at any period of the acute stage. This is rare and of a grave prognosis. 4. Albuminuria of convalescence, which should be divided into two varieties. The first accompanies or precedes the febrile returns of convalescence, or a tardy complication: abscess, parotiditis, etc. It is transitory, little abundant and without serious prognosis. The second is analogous to post-scarlatinal albuminuria and, like this, proceeds from a particular form of nephritis termed variolic nephritis, the anatomo-pathological characters of which have been lately studied by M. S. Renault, of Lyons. The pathogenic conditions which favor the appearance of albuminuria are still rather obscure. The examination of the greater part of observations published leads to this eclectic conclusion, that the two principal predisposing factors of secondary variolic albuminuria are the intensity of the malady on the one hand, and the bad gen-

eral condition of the patient on the other. As to the exciting cause, it is not precise in any case outside common cold, which figures in all the etiologies. To impute it to parasitism is evidently that which is the most rational in the present state of our knowledge.

In a lecture on the relation of ophthalmic to dental disorders, Dr. Galezowski, the well-known ophthalmologist, dwelt on the close correlation between some eye troubles and caries of the upper teeth. In young children, the slight inflammation and discomforts accompanying the cutting of the first teeth produce keratitis and small corneal ulcers, and these can sometimes be cured by treatment of the teeth. In the shedding of the first teeth a spasm of the eyelids is sometimes observed, which can be removed by extracting the teeth. With the shedding of the wisdom teeth corneal inflammations occur. In adults, the commonest result of dental caries on the eyes is a weakening of accommodation by reflex action through the fifth pair of nerves. Of this the author gives two examples. An American lawyer had had for two years such weakness of accommodation as to make his work almost impossible. There was no hypermetropia or astigmatism, but two of the molars of the upper jaw were decayed and stopped with gold. Dr. Galezowski advised their extraction, and in a few days his patient was able to resume his work. From this it was concluded that the patient's troubles arose from compression of the dental nerve. In another case in which the weakness had lasted for three years, it improved greatly soon after the extraction of a single molar. There was also a case of temporary but almost complete functional blindness following extraction of an upper molar in a man aged 20, who was under the care of Professor Richet at the Hôtel Dieu. Conversely, in a nervous woman, a patient of Galezowski, who had amaurosis of one eye, perfect sight was immediately recovered by removal of a carious molar tooth on the same side.

The *Revue Internationale* has published a note on the proper time for the administration of certain drugs. The alkalies should be taken before meals. Iodine and its derivatives should be taken when the stomach is empty, they are then more rapidly diffused in the blood. During digestion they are decomposed by the acids and starch, and consequently lose their properties. Acids should be administered between meals; if the gastric juice is very acid, they should be taken immediately before meals. Irritant or dangerous substances such as arsenic, copper, zinc, iron, etc., should be taken before meals. The nitrate of silver should be administered before meals. Corrosive sublimate and the greater part of metallic salts should be taken when the stomach is empty. The extract of malt, cod-liver oil, and the phosphates are administered preferably during meals or immediately after.

DOMESTIC CORRESPONDENCE.

LETTER FROM NEW YORK.

(FROM AN OCCASIONAL CORRESPONDENT.)

New York State Medical Association—Puerperal Septicæmia—Are Puerperal Febrile Disturbances due to Microorganisms—The Etiology of Puerperal Fever—Conditions Predisposing to Puerperal Septicæmia—Pathology of Puerperal Septicæmia.

The recent meeting of the New York State Medical Association, which was held at the Hotel Brunswick, October 9, 10 and 11, was a very successful and attractive one. The attendance was somewhat larger than last year, and the banquet on the evening of the second day was a most enjoyable affair. Professor William T. Lusk, of Bellevue Hospital Medical College, was elected President, and Drs. Ferguson and Hinton were, of course, re-elected Secretary and Treasurer. The Vice-Presidents chosen were as follows: First District, Dr. S. H. French, of Montgomery Co.; Second District, Dr. R. C. McEwen, of Saratoga Co.; Third District, Dr. Elias Lester, of Seneca Co.; Fourth District, Dr. T. D. Strong, of Chautauqua Co.

The elaborate programme, that has already been published in *THE JOURNAL*, was faithfully carried out, and, as in previous years, the set discussions on subjects of general scientific interest were the main feature of the session. Probably the most entertaining contribution was the address on Medicine, by Dr. Shrady, who took for his subject, "Medical New York in 1800."

The discussion on *Puerperal Septicæmia* was introduced by Dr. C. C. Frederick, of Buffalo, who stated that as the danger of infection in any case was in direct proportion to the avenues of approach left open for the invasion of sepsis, the importance of prophylaxis was evident. The strictest antiseptic precautions, he thought, should be observed in every case of labor, and among the measures that he advocated was the use of a vaginal douche of bichloride solution (1 to 3,000) before delivery. The placenta should always be removed with the patient on her back, in order to prevent the ingress of air which was likely to take place if she was in Sim's position. After delivery the perineum should be examined, and sutures applied if there was any rupture. If for any reason it was necessary to introduce the hand into the uterus, an intra-uterine injection of bichloride solution (1 to 4,000) should be subsequently employed. He advocated the use of the antiseptic pad, and thought post-partum vaginal injections were unnecessary. When the bowels or bladder were evacuated the patient should be raised to the upright position, in order to drain the uterus and vagina.

As regards the prognosis of puerperal fever, he said that the purely septic forms were the most

dangerous, unless the conditions were promptly and thoroughly treated. When septic germs had once gained entrance into the blood and the lymphatics they were beyond the reach of the physician; but further infection could usually be prevented, and if the patient's strength could be kept up, the hope might be entertained that the poison would be eliminated from the system. He regarded putrid lochia as one of the most potent causes of sepsis.

When septicæmia declared itself vaginal injections of bichloride solution (1 to 2,000) should be employed at intervals of from three to six hours, according to the urgency of the symptoms; and after the use of the douche the patient should be required to sit upright for a moment, so as to drain the parts. All necrosed patches in the genital canal should be touched with a mixture of persulphate of iron solution and compound tincture of iodine, as recommended by Lusk, and if there are any diphtheritic patches, the chloride of zinc should be employed, as advocated by Garrigues. Dr. Frederick thought it probable that the intra-uterine douche had been resorted to too frequently, and that the real benefit in most of the cases when it was used resulted from vaginal irrigation. Among the dangers likely to arise from this practice was one that had been overlooked, viz., that of conveying septic material from the vagina into the cavity of the uterus. If the intra-uterine douche were deemed necessary, the patient should be placed in the lithotomy position, and from one to three pints of bichloride solution (1 to 4,000) carefully injected. Afterwards the uterus should be squeezed dry, a pencil of iodoform inserted into its cavity, and a dose of ergot administered to insure contraction. In controlling high temperature antipyrin, and preferably antifebrin, was frequently of service.

The first question propounded, *What facts can be cited in support of the doctrine that the puerperal febrile diseases owe their origin to the action of microorganisms?* was discussed by Dr. H. M. Biggs, of New York. He said that the natural resistance of the tissues must first be overcome before septic germs could obtain an entrance, and in the normal parturient woman the lochial discharge and the abundant secretions of the parts continually protected the wounded surfaces. The uterus was also kept tightly closed by its own contractions, and the epithelium of its cavity occluded its orifices with an impenetrable shield. If, however, anything occurred to diminish the quantity of the lochia—if the uterus did not contract properly, if the vital resistance of the tissues are reduced by depressing influences of any kind, or if portions of membrane or blood-clot were retained in the uterus, and if under any of these circumstances microbes were introduced, it was evident that the most favorable conditions for the development of puerperal septicæmia were present.

With these points in view, it was easy to understand how the use of antiseptic precautions was so efficient in preventing this condition. If, in the first place, an antiseptic vaginal douche was employed during and immediately after labor, and if, in the second place, an antiseptic dressing were kept applied after delivery, impaction was much less likely to occur than if these measures were not resorted to, and if it did occur, it was apt to do so at a later period, when a better opportunity was afforded for counteracting its effects. The different conditions met with in different cases explained the various forms of puerperal septicæmia met with. After death pyogenic organisms had been met with in the milk-glands, in the lymphatics, and in the various organs throughout the body, and it had been demonstrated that they were eliminated during life by the kidneys and other excretories. The *streptococcus pyogenes* was found in a large number of cases, and it was probable that this microbe was identical with the *streptococcus* of erysipelas. The next most common bacillus met with was the *staphylococcus*, the ordinary microbe of suppuration.

The puerperal febrile diseases were, therefore, a class of affections closely allied to infectious surgical diseases. The bacilli of the latter were known to be capable of producing all the conditions met with in puerperal septicæmia. The abolition of the latter from maternity hospitals constituted one of the most remarkable chapters in the history of bacteriology, and hence the conclusion could not be avoided that these diseases were of bacterial origin.

The second question was, *Is there a specific febrile disease peculiar to the puerperal woman, or are the various forms of puerperal fever the result of septic or putrid infection similar to or identical with that familiar to surgeons as septicæmia? What etiological relations exist between the zymotic diseases and some forms of puerperal febrile diseases, and in what manner are the zymotic modified by implantation upon the puerperal state?* It was discussed by Drs. E. D. Ferguson, of Troy, and S. B. W. McLeod, of New York. Dr. Ferguson said that he had no hesitation in answering the first part of this question in the negative. In our present state of knowledge the theory that puerperal fever is a specific disease seems no longer tenable, and at the last important discussion on the subject in this country, viz.: that before the New York Academy of Medicine in the winter of 1883-4, the only participant who advocated the specific character of the affection was Dr. Fordyce Barker. When fever occurred *ante-partum*, as was undoubtedly occasionally the case, it was more reasonable to suppose that it was due to some of the causes which might give rise to pyrexia at any time, rather than to a specific puerperal fever without any anatomical basis.

As regards the second part of the question, he said it could be shown that pregnancy did not afford immunity from any of the zymotic diseases. It was necessary to distinguish between those cases in which the zymotic disease complicated the puerperal fever, and those in which the zymotic infection gave rise to the puerperal fever. With regard to diphtheria, he desired to enter a protest against regarding every case of membranous exudation as one of true diphtheria. The zymotic diseases were apt to be more or less modified by implantation on the puerperal state, and the mortality was often increased, especially when pelvic inflammation was present. The diminution of the red corpuscles and the increase of fibrin in the blood resulting from pregnancy might perhaps explain to some extent the greater severity of the zymotics, as a rule, in parturient women. In cholera, however, the mortality was apparently not increased in pregnant women. Small-pox was noted for its mortality in this class, the death-rate ranging from 20 to 40 per cent. It frequently caused abortion, which was apt to be followed by the death of the patient; and the same was true of scarlatina and measles. The relation between erysipelas and puerperal fever had long been well known. This disease was not so fatal, however, if care was taken to avoid infection of the genital tract.

Dr. McLeod said in the course of his remarks that it might in general be stated that puerperal fever was a complex disease, depending on a variety of causes, although dependent in most cases on surgical septicæmia. The test of treatment, as shown by the remarkable success of antiseptic midwifery, conclusively proved this.

Drs. F. W. Ross, of Elmira, and John Shrady, of New York, discussed question 3: *What conditions of the woman predispose to the development of puerperal septicæmia? To what extent are the accidents of childbirth, together with the manipulations of the accoucheur, to be considered as etiological factors in puerperal infection? Are there any antiseptic measures before, at, or after labor, under any and all conditions or complications, that may be relied upon as prophylactic to puerperal septicæmia?* Dr. Ross said that no iron-clad rules could be laid down for prophylactic treatment, but the observance of certain measures, with due regard to the condition and surroundings of the patient, would, in general, be of service. In the first place, the woman should be placed in the most perfect health attainable, both general and local, before her confinement. At the time of labor she should have plenty of pure air, and all things about her should be scrupulously clean; efficient antiseptic solutions being employed to secure this end. If the perineum were ruptured, either sutures should be put in or antiseptic protection afforded to the parts. Antiseptic injections might be judiciously used, if called for, before, during or after labor.

Dr. Shrady said that one of the most important predisposing conditions was a lowered vital tone; and this view was supported by the bacterial origin hypothesis, because it was well known that healthy tissue constitutes the great barrier against microbic infection. The primary channel of infection was the genital tract, and experience had taught the advisability of making infrequent vaginal examinations.

The question, *What is the pathology of each of the several forms of puerperal septicæmia? What conditions or circumstances incident to puerperal septicæmia, and what forms of the disease, tend to render it fatal?* was discussed by Dr. Frank Graaer, of the Carnegie Laboratory. Drs. Wm. T. Lusk, of New York, and R. L. Banta, of Buffalo, discussed the last question, which was as follows: *What plan of antiseptic treatment can be employed with a large degree of success in each of the several forms of the disease? Does every rise of temperature above 100° F. in the puerperal woman constitute an indication for immediate resort to irrigation? When should irrigation be intra-vaginal and when intra-uterine? When irrigation is employed, how often should it be done, and when should it be discontinued? What hygienic, medicinal and dietetic treatment is to be used, in addition to the local antiseptic measures? To what extent should alcoholic stimulants and antipyretics be used?*

Dr. Lusk said that in the midwifery of the future there was reason to believe that there would be no occasion whatever to discuss the treatment of puerperal septicæmia. In his opinion this condition ought never to follow a properly conducted labor. In the Emergency Hospital in New York, where the number of confinements averaged 220 annually, the mortality from puerperal septicæmia had been reduced to *nil*, and it was actually the case at the present day that the women confined in lying-in institutions fared better as regards this affection than private patients surrounded by all the aids that wealth can command. The very fact that a place was given to such a discussion as this on the programme of the Association, showed, indeed, that the necessity and efficacy of preventive treatment were not yet as fully appreciated by the profession at large as they ought to be; and he could not but believe that one reason why this was so was because that when antiseptic prophylaxis first came in vogue it was taught that the removal of the carpet, upholstery, etc., from the chamber, and other such extreme measures, were required, and the difficulty of carrying out such a plan of procedure, which was altogether unnecessary, had proved a stumbling-block to many practitioners.

In the first place, both the physician and the nurses should understand the necessity of surgical cleanliness, and soap and water and corrosive sublimate be the means by which this could best be obtained. The hands and forearms should be

washed with bichloride solution, just as if laparotomy were to be performed, and the patient's genitals, abdomen and thighs should also be bathed with it. Vaginal injections with the bichloride solution during labor are a valuable safeguard against self-infection. All unnecessary manipulations, such as attempts to dilate the cervix with the fingers, should be avoided. The complete removal of all the membranes should be carefully looked to in the third stage of labor, and Dr. Lusk said that in order to secure this he always employed a strong light so that he could readily see what he was doing. If it was necessary at any time to introduce the hand into the uterus the cavity should be afterwards washed out with a solution of carbolic acid.

To prevent germs from entering the tissues to dangerous extent, nothing, he said, would seem, at first sight, so efficient as irrigation; but uterine irrigation was not devoid of risk, and this method of procedure really left out of account the great bulk of puerperal inflammations. Experience had shown that if the uterine douche were employed regularly at four hours intervals the mortality would be considerable. It was a point worthy of note that a rise of temperature did not constitute at all the indication for a resort to uterine irrigation. The true indication was a large, flabby uterus, with retained membranes, portions of placenta, or blood-clots.

In using the uterine douche a glass tube was preferable, and carbolic acid solution was the most satisfactory fluid for the purpose. It should be preceded by a vaginal douche, and the quantity of fluid employed should not be large—never exceeding two quarts. The stream should be continuous, and not interrupted. It was important that a free exit for the fluid should be secured, and after the douche had been finished pressure should be made upon the uterus to facilitate contraction and the expulsion of any of the solution that might remain in the organ. He had found it a good plan to have a pencil containing a drachm and a half of iodoform in the cavity of the uterus. The mistake was often made of resorting to the uterine douche too frequently. It was his practice to give a second douche at the end of twelve hours, if it was required; but a third was rarely needed. Dr. Lusk stated that he still had faith in the efficacy of the vaginal douche in almost all the varieties of puerperal fever, as it certainly promoted uterine contraction, and was generally very agreeable to the patient.

In every case of increased temperature after parturition the first thing to do was to make a careful examination of the vulva and vagina, and if ulcerations were found to apply caustic. The use of ice-bags on the pelvic region was generally of service. The chief danger in puerperal septicæmia was from weakness of the heart's action, and this was to be counteracted by alcoholic stim-

ulus, abundant liquid food, and such agents as strophanthus. In all cases of fever following parturition suitable nourishment and alcohol were indispensable. The most careful attention to the hygienic surroundings of the patient was, of course, called for. In the severest cases the ice-coil was undoubtedly useful, and Runge had recently reported very favorable results from the employment of tepid water in lymphatic septicaemia. These results were the more remarkable from the fact that this was the most fatal variety of puerperal fever, and the method was certainly worth trying.

P. B. P.

The Acid Treatment of Yellow Fever and other Fevers, and Scorbutic Conditions Generally.

Dear Sir:—In view of the ravages of yellow fever in the South and elsewhere, it is the bounden duty of physicians to resort to all promising means of relief to prevent and stay its destructive course, and for this purpose I desire to invite attention again to the great value of the acids and acidulous substances in the hygienic and medicinal treatment of all such diseases, and particularly to the superior sanative properties of nitro-hydrochloric acid as a germicide, antiseptic, febrifuge, alterative, hæmostatic, tonic, etc., in contagious, infectious and pernicious fevers, as well as analogous diseases, both internally and externally, as a prophylactic and curative. I can truly testify to the great practical utility of nitro-hydrochloric acid in inflamed and festering throat, diphtheria, scarlet, variolous, puerperal, typhus, ship, malarial, bilious, and other fevers, with their allied toxic, putrid and scorbutic conditions, constitutional and local, but have had no practical experience with it in yellow fever, though I believe it will prove equally efficient therein as in the former. For a general summary of its medical properties and applications I refer to my previous article thereon, in *THE JOURNAL*, vol. x, p. 65.

Both as a preventive and remedial agent nitromuriatic acid is very efficacious in all such diseases, and may be taken freely in doses of from two to four drops of the strong acid in water or lemonade, through a glass, straw, or other non-corrosive tube, except in edentulous children and adults, by draught or sipping a little at a time, as a refreshing, purifying beverage and healing medicine, according to necessity. It is simple, safe, properly diluted, prompt, active, cheap, and easily procurable almost everywhere. It will not interfere with the usual remedies except in the case of calomel, which it converts into corrosive sublimate, and would thus prove dangerous in undue quantities, but in small doses beneficial, as it is compatible with hydrarg. bichloride, which might be substituted for the calomel, it being also

a powerful germicide, alterative and resolvent, and the two together would be doubly remedial.

Other acids, mineral, vegetal and animal, as muriatic, nitric, sulphuric, bromohydric, phosphoric, salicylic, etc., and lemonade, vinegar, sour buttermilk, with acid fluids, fruit, and food generally, sweetened to taste, are also applicable according to special indications. I firmly believe that the acid regimen and medication will greatly mitigate if not absolutely avert and resolve the scourge of yellow fever, with all other contagious, infectious, and pernicious fevers, and scorbutic conditions, hence strongly urge their use therein, both for preventive and curative purposes.

GEO. J. ZIEGLER, M.D.

Philadelphia, Sept. 30, 1888.

Abortion Laws.

Dear Sir:—In your most able and kindly editorial on "The Ethics of Marriage," in *THE JOURNAL* for September 1, there has, in some way which I cannot understand, crept in a mistake as to the abortion laws referred to in the tabular view in the appendix. I notice that a correspondent in your issue of September 22 naturally feels aggrieved at the seeming aspersion on his State.

This tabular view shows that thirty-eight States and Territories punish the attempt to perform abortion, and no less than eighteen punish advertisements looking to that end. The book has already—since May—passed into a second edition, and at first I thought the tables might have become confused in this, but, referring to a copy lately received from the publishers, I find them all right.

Will you kindly make correction in some future issue of *THE JOURNAL*, and greatly oblige Yours truly,

H. STERLING POMEROY, M.D.

341 Boylston St., Boston, October 12.

BOOK REVIEWS.

TRANSACTIONS OF THE MEDICAL SOCIETY OF THE STATE OF PENNSYLVANIA, at the Thirty-ninth Annual Session, held at Philadelphia, June, 1888. Published by the Society. 8vo, PP. 355.

The first literary contribution to this volume is the Presidential Address of Dr. Richard J. Levis, on "Traditional Errors of Surgery." Among the traditional errors pointed out are those pertaining to the differentiations of surgical practice called specialism. "The greatest advances in surgical science and art, at the present time, are made through special attention to certain lines of study and practice. This differentiation by specialism is justified by the advance of these lines beyond the possibility of any indi-

vidual practitioner ever comprehending all that can be known in them." Specialism must be intelligently guarded, however. It is a superstructure that must be built on a substantial generalism. As Virchow has said: "No specialty can flourish which separates itself from the common source of science. The great specialists, whose labors have borne most fruit, and added most to the stock of human knowledge, have been the men with a solid foundation of generalism. Dr. Levis recognizes this, and points out that the great danger of specialism lies in *exclusivism*—the study of and practice on distinct organs of the body without reference to their mutual and intimate relations and interdependence.

Dr. Levis then refers to the violent opposition to anæsthesia in 1846, to the denunciation of ovariectomy and ovariectomists, to the tardy recognition of Lister's principles of antiseptic surgery, and to the general tendency to make complicated surgical instruments and apparatus.

The addresses in medicine, by Dr. Edward R. Mayer, of Wilkesbarre, in Hygiene by Dr. Traill Green, of Easton, in Obstetrics by Dr. Parvin, in Mental Disorders by Dr. H. C. Wood, and in Otology by Dr. Alexander Randall, are well worth reading.

Dr. Frank Woodbury contributes a paper on "The effervescent form for the administration of certain remedies;" Dr. R. Lowry Sibbet one on "Decisions of the Courts relating to the Registration Act of 1881," in which he urges the necessity of a State Board of Medical Examiners. "The Proposed State Board of Medical Examiners" is the title of a paper by Dr. John H. Packard. Dr. Lawrence F. Flick contributes an admirable paper on "The Contagiousness of Phthisis," though we may not be prepared to accept his conclusions. A very interesting paper is one by Dr. Hugh Hamilton, on "The Chemical Factor in Disease." Dr. Mordecai Price has a short paper on "Removal of the Kidney for Traumatism," and Dr. John B. Deaver one on "Nephrectomy for New Growths." Dr. S. F. Davis makes an interesting report of a case of *removal of the uterine appendages as a remedial measure*. Dr. J. H. Musser read a memorandum of the life and works of Benjamin Rush. Dr. William F. Waugh read a paper on the "Specific Treatment of Typhoid Fever"—by sulphocarbonate of zinc, the use of which he believes is a legitimate deduction from the pathology of the disease.

Dr. Thomas D. Dunn read a paper on "The Hypodermic Use of Cocaine in Migraine and Bronchial Asthma," Dr. E. A. Wood, of Pittsburgh, one on the "Irrational Use of Commercial Pepsin," Dr. J. Chris. Lange, of Pittsburgh, one on "Some Influences of Diseases upon the Mind," Dr. Louis J. Lautenbach one on the "Prevention

of Ear Disease, by Care exercised particularly in Childhood," Dr. Charles H. Burnett one on "Aural Vertigo," one on "Gouty Sore Throat" by Dr. Harrison Allen, Dr. A. G. Heyl one on "Two Retinal Symptoms in Brain Disease," and Dr. Chas. M. Dulles made a "Report on Hydrophobia."

The Pennsylvania State Society has just grounds for pride on account of the unusual excellence of the papers in this volume.

The Physicians' Leisure Library. THE INFECTIOUS DISEASES. By CARL LIEBERMEISTER, Professor of Clinical Medicine in Tübingen, Germany. Translated by E. P. HURD, M.D., Newburyport, Mass. With Notes and Appendices. Small 8vo, 2 vols., paper, pp. 141, 269, Detroit: Geo. S. Davis. Chicago: W. T. Keener. Price, 25 cts. each.

Dr. Hurd has contributed in no small degree towards bringing the writings and teachings of foreign medical men within the reach of Americans that do not read a foreign language, and his work has the peculiar merit of instructing the reader without allowing him to be aware that he has a translation.

The first volume of the work before us deals with the miasmatic and miasmatic contagious diseases; intermittent fever and typhoid fever. It should be said that the scope of the work is "The Pathology and Treatment of Infectious Diseases." Every one that has read anything from Liebermeister's pen knows that he is one of the strongest adherents to the germ theory of disease. To prevent making the present volumes too bulky the translator has omitted Liebermeister's chapter—a long one—on the nature of infection. In his appendix to the chapter on Malaria Dr. Hurd has wisely added some notes setting forth the treatment of intermittent fevers as practiced in this country; and as appendices to the treatment of typhoid fever he has made some notes in regard to the cold-bath treatment of typhoid fever, and has added a summary of the treatment of this disease in some of the principal American Hospitals.

The second volume deals with measles, scarlatina, smallpox, vaccinia, varicella, rubella, diphtheria. Dr. Hurd has also added to the value of this volume by notes.

On the whole one must commend this work from the pen of one of the masters of medicine, and so intelligently edited.

OPIHTHALMIC SURGERY. By ROBERT BRUDENELL CARTER, F.R.C.S., etc., and WILLIAM ADAMS FROST, F.R.C.S., etc. With a chromo-lithograph and 91 engravings. 8vo, pp. 554. Philadelphia: Lea Brothers & Co. 1888. Chicago: A. C. McClurg & Co.

The authors have divided their book into fifteen chapters. The first deals with the anatomy and

physiology, the second with the examination of the eye. The other chapters are devoted to the affections of the various tissues of the globe and its adnexia. An appendix contains Snellen's Distance Types, Reading Types, Army and Navy Test Dots and Formulæ.

The book is well written. It is concise and abreast of the times. Drs. Carter and Frost have not limited themselves to outlining the successive steps in the advancement of our science, but discuss leading questions and clinch arguments by an array of numerous interesting questions and opinions, the result of long experience.

Dr. Carter is opposed to the new method of after-treatment in cataract extraction. He claims it is only a resuscitation of a procedure in vogue twenty-five years ago, which was condemned by Graefe, the originator of the pressure bandage. The author says, "The advantages to a healing wound of complete shelter and of gentle, uniform support is self-evident." The present method of operating for cataract without iridectomy is also denounced as an error and a departure from a reliable and safe method.

In the chapter devoted to advancement of the recti muscles allusion is made to the operation devised by Dr. Prince, of Jacksonville, Ill., erroneously located in Philadelphia. Prince's plan is slightly modified by the employment of only one suture, which after having transfixed conjunctiva and sub-conjunctival tissue is passed from without inwards through the upper part of the muscle and then again from within outwards through the lower part of the rectus. This brings the vertical portions of the thread, forming a rectangle, underneath the conjunctiva, the horizontal parts above that tissue. The ends of the thread are then tied, advancing the muscle and entirely covering the seat of operation.

The work abounds in good practical suggestions. It will prove especially welcome to the student owing to its completeness and terseness. It bears the stamp of originality, and consequently will be interesting and useful to physicians and specialists.

A MANUAL OF GENERAL PATHOLOGY. Designed as an introduction to the Practice of Medicine. By JOSEPH FRANK PAYNE, M.D., Oxon, F.R.C.P., etc., with 153 Illustrations. 8vo, pp. 560. Philadelphia: Lea Brothers & Co. 1888. Chicago: A. C. McClurg & Co.

The plan of this work is somewhat different from others that have the same title. The first half of the volume is devoted to a brief review of the topics usually described in works on general pathology, and the second half to a description of the causes of disease and their mode of action.

In the first portion we are glad to see chapters devoted to "pathological relation of blood-pressure" and "fever." These are subjects too

frequently omitted from similar works. Inflammation is not considered by the author a conservative process. In his opinion, "inflammation is damage." The chapter on fever is a brief but fair review of the modern literature of the subject.

The second portion deals with topics of very great interest. Although nearly one-half of the volume is devoted to it, many of the topics are discussed too briefly, and many should be added to make it complete.

This work does not duplicate any other. It is excellent for what it purports to be, a Manual of General Pathology designed as an INTRODUCTION to the Practice of Medicine. It should not be used to displace other text-books on Pathology, but rather to compete with the early chapters of works on Practice of Medicine, which have been entitled by the older writers principles of medicine.

THERAPEUTICS. Its Principles and Practice. By H. C. WOOD, M.D., LL.D., etc. Seventh Edition of a Treatise on Therapeutics rearranged, rewritten and enlarged. Philadelphia: J. B. Lippincott & Co. 1888. Chicago: W. T. Keener.

This work of Dr. Wood's has become a classic, and the appearance of each new edition is looked for by the profession and by students of medicine with pleasure, for as an authority it is unquestioned. The present edition is so different in title, arrangement, and in the extensive revision of old matter and addition of new, that it marks an epoch in the history of the work.

So well known is this treatise that detailed notice is not necessary. We will remark only on a few of the most conspicuous changes. The title of the book is the first of these changes to attract attention. Very much more space is allotted to measures of treatment not medicinal than in former editions, and this part now constitutes the first division of the work instead of the last.

The classification of drugs has been considerably modified. For instance, quinine appears under the head of antiperiodics instead of tonics, and a group of antipyretics follows that of antiperiodics. It need not be said that most excellent descriptions of the physiological and therapeutic action of all the new drugs that can be considered reliable have been introduced.

MISCELLANEOUS.

TREATMENT OF FOUL SHIPS.—The Surgeon-General of the U. S. Marine-Hospital Service has issued the following circular to Medical officers of the Marine-Hospital Service, and others whom it may concern:

In order to stimulate ship-masters to aid in securing a clean ocean-going fleet, the following regulation concern-

ing the treatment of foul ships is hereby adopted, and will be observed at all National Quarantine Stations :

1. When a vessel arrives at any National Quarantine Station from an infected port, and requires disinfection, she will be subjected to *ordinary disinfection*, as provided in former regulations.

2. When any vessel shall arrive at a National Quarantine Station in such foul condition as to render her dangerous from a sanitary point of view, and is found to require cleansing and disinfection, having at any former time within one year been subjected to ordinary disinfection, such vessel will be required to undergo *extraordinary disinfection*, which, in addition to the ordinary measures will include holy-stoning, scraping, the taking out of rotten wood, a second disinfection, and interior repainting, all of which will be required before granting a certificate of free pratique.

CREMATION IN BUENOS AYRES.—During the past year 993 bodies were cremated in Buenos Ayres, of which number 742 were of persons dead of cholera, small-pox, and other contagious diseases.

THE REFORM OF CIRCUMCISION.—The Israelites of Paris recently appointed a commission of surgeons under the presidency of Zadoc Kahn, the Grand Rabbi, to consider what modifications might advantageously be introduced in the ritual of circumcision. They have published rules looking to more thorough cleanliness of the operator, of his instruments, and of the infant, and have decided to do away with the sucking of the wound after the operation.—*The Annals of Hygiene*, Oct., 1888.

A FEE OF £10,000.—Surgeon-Major Freyer, M.D., I.M.S., has received a fee of one lakh of rupees (£10,000 sterling) from H.H. the Nawab of Rampur, as a token of esteem as well as an acknowledgment of his valuable services in the successful treatment of himself and General Azimuddin Khan, the popular head of the Administrative Agency of the State, who had suffered for nearly three months from a malignant rheumatic fever; his recovery has been the occasion of great rejoicing at Rampur. This is said to be the largest fee ever received by a medical practitioner in India, and probably has never been exceeded in any country.

MEDICAL EDUCATION OF CHINESE IN CHINA.—Dr. W. W. Myers' three pupils, who have completed a course of four years' instruction under his direction at Formosa, recently passed an examination in Shanghai. The result, with the percentage gained at the primary examinations in Hong Kong and Shanghai, was as follows: Goh Kit-moh, 72 per cent.; Chan Ching-hai, 68 per cent.; Li Tsun-fan, 66 per cent. Following the presentation of diplomas a detachment went through ambulance manœuvres, stretcher drill, dressing the wounded, and applying splints adapted from the Chinese umbrellas.—*The British Medical Journal*, Oct. 6, 1888.

DR. CHARLES W. PURDY will return from Europe about November 1.

DEATHS FROM CHLOROFORM.—During 1885, 1886 and 1887, nine persons died in Australasia while under the influence of chloroform, four of the cases being in Sydney.

PROFESSOR FR. SCHULTZE, of Dorpat, will take the chair at Bonn made vacant by the death of Prof. Rühlé.

DR. PAGLIANI, Professor of Hygiene in Turin, has been appointed Director of the Institute of Experimental Hygiene in Rome.

Official List of Changes in the Stations and Duties of Officers Serving in the Medical Department U. S. Army, from October 6, 1888, to October 12, 1888.

Major John W. Williams, Surgeon, on duty with batal-

lion on Second Artillery, now at Ft. Wadsworth, New York Harbor, is granted leave of absence for one month, with permission to apply to the proper authority for an extension of one month. Par. 1, S. O. 209, Hdqrs. Div. of the Pacific, Governor's Island, New York City, October 4, 1888.

Major Frank Meacham, Surgeon U. S. Army, died at Ft. Douglas, Utah, October 9, 1888, at 1:20 P.M.

By direction of the acting Secretary of War, the following named officers of the Medical Department will report in person, on the dates set opposite their respective names, to the President of the Army Medical Examining Board, Army Building, New York City, for examination for promotion: Capt. James C. Merrill, Asst. Surgeon, October 16, 1888; Capt. George McCreery, Asst. Surgeon, October 16, 1888; Capt. Richard W. Johnson, Asst. Surgeon, October 9, 1888. Upon completion of their examination the officers named will rejoin their proper stations. Par. 5, S. O. 231, A. G. O., October 4, 1888.

Capt. William B. Davis, Asst. Surgeon U. S. Army, is granted leave of absence for six months, by direction of the acting Secretary of War. Par. 12, S. O. 232, A. G. O., October 5, 1888.

Capt. John M. Banister, Asst. Surgeon, leave of absence granted in S. O. 210, September 10, 1888, from this office, is extended one month, by direction of the acting Secretary of War. Par. 2, S. O. 232, A. G. O., October 5, 1888.

By direction of the acting Secretary of War, Capt. Louis H. Maus, Asst. Surgeon, is relieved from duty at Ft. Schuyler, N. Y., and will report in person to the commanding officer, Ft. Porter, N. Y., for duty at that post. Par. 10, S. O. 236, A. G. O., Washington, October 10, 1888.

Capt. William G. Spencer, Asst. Surgeon U. S. Army, is granted leave of absence for two months, by direction of the acting Secretary of War. Par. 11, S. O. 236, A. G. O., Washington, October 10, 1888.

Official List of Changes in the Medical Corps of the U. S. Navy for the Two Weeks Ending October 13, 1888.

Medical Inspector Adrian Hudson, ordered to Naval Hospital, Mare Island, Cal.

Medical Director A. L. Gihon, detached from the Naval Hospital, Mare Island, Cal., and proceed home.

Medical Inspector N. L. Bates, detached from the "Pensacola," and placed on waiting orders.

Surgeon W. G. Farwell, ordered to U. S. R. S. "Franklin." P. A. Surgeon H. B. Scott, detached from the New York Navy Yard, and ordered to the Naval Hospital at Mare Island, Cal.

Surgeon A. F. Magruder, ordered to duty at Headquarters of the Marine Corps.

Official List of Changes of Stations and Duties of Medical Officers of the U. S. Marine Hospital Service, for the Four Weeks Ending October 6, 1888.

Surgeon George Purviance, to proceed to Washington, D. C., for special duty. October 3, 1888.

Surgeon G. W. Stoner, detailed as chairman of board to select site for marine hospital at Evansville, Ind. October 5, 1888.

Surgeon C. B. Goldsborough, leave of absence extended fifteen days on account of sickness. September 28, 1888.

Asst. Surgeon Seaton Norman, detailed as recorder of board to select site for marine hospital at Evansville, Ind. October 5, 1888.

Asst. Surgeon J. B. Fattie, to rejoin station at St. Louis, Mo. October 5, 1888.

Asst. Surgeon G. M. Magruder, to proceed to Way Cross, Ga., for special duty. September 15, 1888.

Asst. Surgeon H. D. Geddings, to proceed to Camp Perry, Fla., for special duty. September 15, 1888.

THE MANAGEMENT OF EXTRA-UTERINE PREGNANCY.

Read in the Section on Obstetrics and Gynecology at the Thirty-ninth Annual Meeting of the American Medical Association, Cincinnati, May, 1888.

BY A. W. JOHNSTONE, M.D.,
OF DANVILLE, KY.

The history of the management of extra-uterine pregnancy, like every other conception which has finally resulted in good to the human race, begins with very crude—I might almost say utterly empirical manœuvres. Slowly it has emerged from its horribly uninviting chrysalis to its crawling caterpillar stage, which is almost passed, and its bright-winged life has now really begun.

Passing over without mention the mistakes and blunders of those who used to evacuate the amniotic fluid, and those who once injected substances into the gestation sac, as well as that later and better procedure, elytrotomy, let us go at once to the discussion of the only two methods which now receive much recognition from the medical world, which are electricity and abdominal section.

Let me state clearly and distinctly in regard to the electric current in all its forms, that I believe it wrong in principle, dangerous in practice, and frequently disastrous in its final results.

One of the assumptions of the originators of the electric treatment was that all one need do to stop the development of the gestation sac, was to kill the fetus, believing that on its life alone depended not only the secretions of the amniotic sac, but the growth and development of the placenta. That they in reality were nothing but what their ordinary names, foetal appendages, indicate, and that, like the nails and hair to the general body, the death of the embryo meant the immediate dissolution of all. This, however, thanks to Berry Hart, Knowsley Thornton and Tait, we know is not true, for the placenta frequently will live on, and continue developing, long after the premature death of the fetus.¹

This agrees most fully with all my studies on the endometrium, the published results of which

are contained in my papers on "The Menstrual Organ," "The Endometrium in the Cycle of the Gut," and "The Infantile Uterus." The central idea that runs through them all is, that the placental matrix has an entirely separate and distinct physiological existence from all other organs, and that its function is to take up and nourish the ovum, which is done entirely independently of control from any other source than its own nerve supply.

It is true this nourishment cannot be done until the ovum is present; it is also true that the mill cannot grind without the wheat, but no one would think for an instant that the wheat controlled the movements of the mill. In the intra-uterine condition we have a totally different state of affairs from that of the ectopic form. In the latter we have the placenta developing from the adenoid layer of the tube, but we do not have it surrounded by a powerful muscular sentinel, who is ready, on the slightest indication of anything wrong, to expel the whole of the new development.

How frequently it is our experience to find signs of life in only two or three months' abortions; so much so, that it is an egregious blunder to think every miscarriage is due to some error either in the fetus or placenta, for experience has long since taught us that repeated abortions are due as much to some conditions in the uterine wall, as they are to diseases of either the fetus or placenta.

In extra-uterine pregnancy, however, an abortion is impossible. The placenta, once started, must go on until it has finished its physiological life, the limit of which is nine months. It is the gradual death of the placenta that causes the terrible struggles of the extra-uterine fetus, at the close of the false labor, which, so far as the child is concerned, is nothing more or less than a slow asphyxia.

Thus I am thoroughly convinced that, to stop the growth of the ectopic gestation sac, it is necessary not only to kill the fetus, but also to shock the pelvic sympathetic so thoroughly as to cause an interference with its control and produce what, in intra-uterine conditions, would result in a menstrual decidua. Thus, gentlemen, you see why it is that the reported cases of electric treatment of extra-uterine pregnancy are so stubborn in

¹ Tait. American Journal of Obstetrics, April, 1885, p. 394. Berry Hart. London Obstetrical Society.

their resistance, and you see the reason for the necessity of so many repetitions of those terrible doses of electricity before there is any appreciable diminution in the tension of the sac. In all probability most children are killed by the first application, but it is the placental membranes which keep up the secretion of the amniotic fluid, and it is them you must kill before any diminution can be looked for.

Thus it seems to me to be fully demonstrated that it is not the foetal, but the maternal nervous system which must be overpowered by the battery, and for this reason I believe that the whole practice is founded on a dangerous error. Another of their assumptions, from personal experience, I can assert most positively is wholly wrong, and that is as to what the so-called "premonitory symptoms" mean.

On page 293 of the *Transactions of the American Gynecological Society*, for 1887, you will find a discussion of this subject, introduced by our honored chairman, in which all but Dr. J. E. Janvrin concurred in the belief that the "colicky pains," and "first slight shocks," are due to contractions of the tube, or movements of the foetus. He, however, took the ground that they are due to the giving way of some structure, and that in most cases it is accompanied with hæmorrhage to a greater or less degree. His speech closed the half hour allotted for the debate of papers, or I would be on record beside him. But what our President then cut me off from I here wish to say at length, and that is, that Dr. Janvriu's ideas are correct.

I have now, either as assistant or principal, officiated on about six ruptured extra-uterine pregnancies, and in every one of them we found clots of different ages. My own case, published in the *Medical Record* of February 26, 1887, showed this to a very striking degree, but to make sure that I was correct about the cases in which I assisted Mr. Tait, I wrote to him for information on that point, and here is his reply:

"7 THE CRESCENT, BIRMINGHAM, APRIL 12, 1888.

"My dear Johnstone:—To my horror I have just found your letter of February 26, under a mass of papers in my desk, unanswered. It is, I find, the most fascinating occupation that gynecologists can indulge, and just in proportion to their want of experience they dogmatize on such points as this you ask information about. As a rule, there are no symptoms of tubal pregnancy sufficient to call for medical interference, or even examination, until the time of rupture. The proof of this is that, now having seen seventy cases, I have only once had occasion to make an examination before the period of rupture, and then the symptoms were those of ordinary tubal occlusion, nothing to indicate pregnancy. The next time I saw the patient the tube had ruptured. The rupture I

diagnosed, but I thought it was a pyosalpinx which had burst, and caused general peritonitis. I operated immediately and found a large blood clot in the abdomen. I removed the ruptured tubal pregnancy and the patient got well.

"Now if there is anybody else with an experience as large as this who can give evidence to the contrary, we may begin to listen to him, but until such evidence appears, I think it may be reasonably supposed that the opportunities for diagnosis of tubal pregnancy, before rupture, are very rare, and the difficulties of recognition immense. In my preparations the point which you speak of is abundantly proved. There are successive hæmorrhages which leave their relative dates recorded in the altered blood clots. This you saw in your own experience with me here. I don't know how you are getting on with this subject on your side, but here we are going through the stages of the old story. At first the senile authorities stated, of course, that our cases never occurred, and now they are contradicting those of us who have had experience upon the most primitive facts of the record, utterly unable to unlearn their old notions, though following us in the new. It is very likely, of course, to be the same with you.

"I am much interested in what you say about the rush for electrolysis in your country, because here it is already exploded, and will rapidly subside into its original position of rampant quackery. You are at perfect liberty to make any use you like of this letter. Yours ever,

"LAWSON TAIT."

This, I think, places it beyond all doubt that Dr. Janvrin is not alone in the experience which he reports. But to me it is the rule, and not the exception, that when we are first called to cases a slight rupture has already begun. But, as in the one out of seventy which Mr. Tait saw before rupture, it is almost impossible to tell whether the tube contains pus, serum, or a foetus. So, in the use of electricity, we are not only almost sure to begin its use in cases where rupture has already begun, but we can never be absolutely sure that we are not passing it through some inflammatory mass, like that case in which one of my critics² deluded himself into thinking that he had absorbed the whole of a five months' gestation sac, and all in the space of three weeks. Several less lucky cases were brought out in the debate on this subject before the British Medical Association, at its meeting in 1886. Electricity was used on inflammatory masses, and instead of absorption, supuration took place, and prompt laparotomies were all that saved the patients.

Having, as I think, pretty fully shown the errors on which its practice is based, let us turn to the immediate dangers of its use.

Fortunately, the aggregate of the cases on

² The American Journal of Obstetrics, August, 1887, p. 818.

which it has been tried is small, or before this we would have heard of a case of syncope, but to get it, all we have to do is to continue passing these powerful currents through the pelvic sympathetic, and sooner or later we will be sure to find a weakened heart that will not stand it. How many unreported cases like that of Dr. Janvrin the world has contained no one can tell. How many suppurations of effused blood, inflammatory masses, peritonitis, and the like, have been justly chargeable to the electric current, is a question that will probably never be solved, but from Dr. Chadwick's and others' experience with Apostoli's method of managing uterine myomata, to say the least of it, it is a condition in which we would not be at all surprised at having inflammation as a result.

An extra-uterine pregnancy never occurs in a normal tube. Whether you accept the old-time doctrine, that it is always due to a tubal occlusion, or whether you take the theory that it is frequently caused by desquamative salpingitis, which strips the tube of its ciliated epithelium, laying bare its subjacent adenoid layer, which not only robs the ovum of one of its means of transportation, but exposes to its stimulation the natural placental matrix; in either case, we have the gestation sac contiguous to some old inflammatory centres.

We have long since known that weak currents have a considerable absorptive power, but we have also known that strong ones are extremely irritating. So it seems to me that he who passes the full force of a 20-cell battery through a fresh effusion of blood, among a lot of old adhesions and cicatrices, with a possibility of a slight leakage of amniotic fluid, need not be in the least surprised to find a violent inflammation following his manipulations.

But granting that he does find his case before any blood has been effused (which remember, in Mr. Tait's experience has occurred but once in seventy cases), to shake up the smouldering embers of an old conflagration by what is almost a caustic application seems to me, to say the least of it, an extremely daring procedure. It is true that some cases have stood it, but it is also true that pregnant women have been known to fall from the third story, and repair double fracture of both femurs, without aborting, but still we do not consider it exactly the thing to pitch them out of these windows, just to see if they can all stand it.

A case has already been recorded in which a slight rupture was the means of the diagnosis of the case, and in which, in spite of several applications of the electric battery by the best electrician in New York City, the case went on to final rupture and death. I refer to the case of Dr. Janvrin, reported in the *Transactions of the American Gynecological Society* for 1886, and what I believe is that, unless we stop the use of the electric battery, it is only a question of time until

others will be placed beside it. Thus my reasons for believing it is immediately dangerous in practice are, that weakened hearts will not stand the currents we are forced to use, that we rarely ever find a case until a greater or less degree of rupture has taken place, and that the action of these terrible currents on the sac invites the completion of the tears, and that the risk of exciting immediate and violent inflammations and suppurations by thus roughly handling tissues which are already predisposed to them, is, to say the least of it, a very strong possibility.

But the greatest objection of all to the use of the electric current is its remote results. Before we knew anything about tubal diseases, or before electricity was even heard of, it was an established fact that a woman with a dead fœtus in her belly was never out of danger; and now, after all the light that has been thrown on these troubles by the exhaustive study of the various pelvic inflammations, leaving out of sight all the invalidism which they cause, we know that, no matter how many years the mother may survive the fœtus, she is never entirely free from the risk of a septic infection until she is laid away to her final rest.

Cases have been reported of the suppurations of lithopædia after years of apparent quiescence, it is true that such suppurations are very rare, but it is also true that lithopædiæ themselves are now a days seldom formed; many of what used to be called lithopædia we now know to be dermoid production of one sort and another, and by the more advanced methods of managing the pelvis, the errors that lead up to them in Europe are now found and corrected before they are produced, but the mere fact of one of the ultimate aims of electrolysis, being in itself a constant menace to life, seems to me goes a long way to undermine the whole practice.

Long, however, before the fœtus can possibly be calcified is the greatest period of danger. Statistics, like tombstones, can be made to serve almost any purpose, and for that reason I have so far spared you, and do not now propose to inflict upon you any long tables with biased conclusions cut to fit my own ideas, but there is food for thought on this subject which I will give you in a most condensed form from a paper read before the Chicago Gynecological Society last June, by Dr. Bayard Holmes. It is his statistics, which I especially want. He is authority for saying that "Kiwisch collected a hundred cases of extra-uterine pregnancy of all kinds, and it appears from the summary of these cases given by Bandl that about 37 per cent. of these fœtuses became infected, 17 died of peritonitis, more or less acute, four died of peritonitis after the fœtus had long been retained, nine died through long continued suppuration and perforation, seven recovered after spontaneous elimination. Archer collected 132 cases out of which

about 47 per cent. became infected; Parry's cases show about 28 per cent. of those which had passed full term suppurated. During the first year 12 per cent. of the whole number terminated in suppuration, during the second year 5 per cent., during the third year $2\frac{1}{2}$ per cent. After this time less than 2 per cent. were infected each year." This proves conclusively, to me at least, that while the great majority of suppurations occur shortly after the death of the fœtus, and that though the ratio of deaths diminished rapidly after the so called quiescent state has been reached, still the woman must carry a constant source of danger throughout all the rest of her existence, which may explode at almost any time.

Electricians may say it is not fair to quote such statistics on us, for we never practiced electrical treatment, after the fifth month, and that it is only when the pregnancy is small, before the osseous tissues begin to take the place of the cartilaginous, that we hope to get rapid absorption.

In answer to this, though it can be easily shown that you do get suppurations, in Dr. Lusk's historic paper before the British Gynecological Society two years ago, are two deaths of infants at five months, on one of which the electric battery had been used, both of which sloughed out. In the debate referred to on this subject, before the American Gynecological Society last year, Dr. Chadwick, of Boston, reported another, with like results, in which the electric battery had been used, and what is stranger still, the statistics just referred to by Holmes embrace all kinds of extra-uterine gestation. One more entrenchment the electricians may take, and that is in that old exploded idea, that the safest way of getting rid of a dead fœtus is by suppuration. This Lusk shows to be utter folly. So much for the absolute risks to life, but there is still another (and to me an insuperable objection) and that is the months—and even years of invalidism which this method must entail. Now a days, when we have no hesitancy in removing incurably diseased tubes and ovaries, it seems almost like a crime, to allow a woman to carry a tube, which is not only a constant menace to her life, for months a source of pain and wretchedness, and which for years will keep her from her social duties, to say nothing of the repeated monthly congestions and second pregnancy would be almost the signature of her death warrant. Thus, gentlemen, it seems to me, that the leaving of such a condition in any stage of development, can be fraught with little but mischief to the mother, and all her associates.

I must unhesitatingly say that all extra-uterine gestations, up to the fifth month, ought to be removed through an abdominal incision, as soon as found. The very cases, which the advocates

of electricity claim the most for, are the very ones which would be the most easily and safely removed by laparotomy. In proof of this I refer you to Tait's statistics, for I am sure that no other process could possibly have saved as many women, as this last method, which has almost reached perfection at a single bound.

Where a complete rupture has taken place, that is where a vessel large enough to bleed a patient to death, has given way, and which is not held in check by some rapidly adhesive form of peritonitis, not even the most enthusiastic admirers of electricity would for a moment think of using galvanism or of doing anything but following Tait's lead, and when they fully realize that the initial shocks are due to a lighter form of the same condition, I believe they would hesitate before passing their powerful currents through it.

Just on this point let me say that I believe a large proportion of the difference between Tait and his opposers is a misunderstanding in the time when the tear takes place.

Tait knows from his operative experience that the premonitory shocks are nearly always due to a greater or less degree of rupture, and acting on this knowledge, *operates at once*, classing all his cases under the one head of rupture.

The opposite side of the debate, though, assume that these alarming symptoms are due only to contractions of the Fallopian tube, but when they realize, what in this paper I have tried so strenuously to show, that they are in reality dealing with rupture, I believe they will find themselves not so very far after all, from the ground on which Tait has built an everlasting monument. Though leading the van, Tait is not alone in successful European work, on extra-uterine pregnancies, for Berry Hart, Martin and others have reported almost equally good results, and I am glad to say that the profession on this side of the Atlantic are waking to the necessities of the case.

Since the report of my success, cases have been reported by S. C. Gordon, of Portland, Maine; Joseph Price, of Philadelphia, Pa.; William Gardner, Montreal, Canada; G. M. Tuttle, of New York City, and Charles B. Penrose, of Philadelphia, all of which go to show that there are laparotomists in this country that can do the work successfully when they have the opportunity.

But for the exact status of the operation in the different countries, let me refer you to that most invaluable work of Greig Smith on Abdominal Surgery.

Up to the period of the fifth month, I doubt whether elytotomy ought ever to be done, and after that time I am sure its usefulness will be extremely limited, but we may occasionally find badly neglected suppurating cases, in which we are bound to open them, at the places where they

are about to point, and this will sometimes necessitate an elyototomy. But as the world grows wiser, I hope these purulent cases will become like vesico-vaginal fistula, and other conditions which are plainly due to neglect, an almost vanishing quantity. The results of operative interference on a viable foetus, have so far proved disheartening, and as to just what should be done with them, even our most advanced thinkers have not settled to their own satisfaction. It seems to me though, that the longer we let the placenta alone, the wider it will spread out from the centers at which it began, the more numerous its adhesions will become, and the richer will be its blood supply. It is true that a very few of these placentæ reach a higher organization, and when left behind after a laparotomy are gradually absorbed. But their number is so extremely small that I do not believe we ought ever to leave them behind, where it is possible to remove them. My rule, until I see some good reason for changing it, will be in all forms of ectopic gestation, to operate, as soon as I find them, and by these means hope to give the mother the best possible chance.

Martin, of Berlin, has certainly given us, in his one successful "primary" laparotomy, a rule which I think we ought always to attempt to follow, and that is in controlling the blood supply to the placenta, we ought always to apply the ligature to the proximal, and not to the distal part of the vessel.

It is true that in some cases this would be almost impossible, but in many others we would be able to get at the broad ligaments, and thus cut off the blood current before it reaches the soft, treacherous tissue, which lies just underneath the placenta. In closing let me state that after a careful study of the subject, I am convinced that laparotomy is the only thing which ought ever to be thought of as a cure, for extra-uterine pregnancy, and that the time to operate is as soon as possible after its discovery, and if we do not use exploratory incision to clear up our doubtful cases, we are in great danger of letting our patients die without thoroughly understanding the cause of death.

When I began the preparation of this paper I thought I was almost alone in this country in the extreme ground, that a tube containing a small foetation, ought to be removed as soon as discovered without any further meddling, but I have just seen Dr. Janvrin's paper, of April 16th, before the New York County Medical Association, which shows that he, and quite a number of the younger members of the profession, are taking the same ground that this paper advocated, and speaks of two cases which have already been done by Drs. Howard, Kelly, and Joseph Price, of Philadelphia.

I do not believe the mortality on extra-uterine

pregnancies, between the sixth and tenth week—where no rupture has occurred—in the hands of first class operators with the proper surroundings, would be as much as one per cent. The truth is the proper management of extra-uterine pregnancy, is still in its infancy, and is not yet free from the encumbrance with which ovariectomy had so long to struggle. It took years, I might almost say generations, for the ovariectomist to learn not to meddle with his cases, until he was ready to take them out, and they have hardly yet got past the tapping age, but when they have reached those Arcadian days when all ovarian tumors are operated on while the patients are strong and well, by trained men, (who do not rush into it merely as a means to advance them in other branches of their practice) but who have given up to it, not only their time, their money and I might say their very souls, I hope the electric battery will have been relegated to its proper fields, and its use as a feticide will be remembered merely as one of the transitional stages, in the developing management of extra-uterine pregnancy.

Danville, Kentucky, May 5, 1888.

THE GREAT VALUE OF A 0.25 D. CYLINDER IN THE RELIEF OF HEAD-ACHE AND EYE PAINS.

Read in the Section on Ophthalmology and Otology, at the Thirty-ninth Annual Meeting of the American Medical Association, May, 1888.

BY JULIAN J. CHISOLM, M.D.,

PROFESSOR OF EYE AND EAR DISEASES IN THE UNIVERSITY OF MARYLAND, AND SURGEON-IN-CHIEF OF THE PRESBYTERIAN EYE AND EAR CHARITY HOSPITAL OF BALTIMORE.

In the selection of cylinder glasses, there is a disposition on the part of many to ignore the lesser degrees of astigmatism, as minor eye defects not worthy of recognition. I have heard often the expression from ophthalmic surgeons, that they never prescribe less than 0.5—D. lens, and am led to the belief that a very large number of young patients are allowed to suffer with eye faults uncorrected, because of this opinion. My practice and teaching for many years has been to recognize irregular refractive faults, however small, and by so doing give great comfort. In fact, I find as the result of my own experience, that these lesser faults are often the most complained of, and that the most marked and annoying reflex troubles are occasioned by the *smaller*, and not by the greater degrees of astigmatism. Pain not restricted to the eyes and forehead, but extending down the spine, disturbing the stomach, and even affecting the limbs, anxious troubles which have resisted the most thoughtful care of the physician and the skill of the gynecologist, have been removed promptly by the use of a 0.25 cylinder lens.

Annoyances from the lower degrees of astigmatism are especially met with among the advanced pupils of the high schools, and more especially in girls. These are often hereditary faults found in the parents as well as in the children: never complained of by the parents who have no cause for eye straining, but brought out conspicuously and annoyingly in the children under forced education. Under the long continued pressure of eye work, which the education of the period demands, very small faults will cause an accumulation of irritation which suddenly explodes, and forces a suspension of study. The continued eye tax of from ten to fourteen hours in the twenty-four will cause the eyes to break down; and then, when the eyes become irritable, even a few minutes of use will bring on eye pains with headache. Eyes heretofore very strong become so sensitive that exposure to daylight is painful, necessitating the use of smoked glasses.

Most of these students have $V. = \frac{2}{3}^\circ$, and can read No. 1 of the test types with readiness. Convex glasses would blur distant vision; a very weak concave might sharpen distant outlines. *The painful eyes of these patients, cured by weak cylinder glasses, show that the apparent perfect vision $V. = \frac{2}{3}^\circ$ is not incompatible with annoying astigmatism, the writings of specialists to the contrary notwithstanding.*

The usual history of such students is, that up to within a short period, they had perfect control of their eyes, and were in the habit of reading all day and half of the night, with only short intervals of rest. Recently when preparing for an examination, which called for an extra amount of application, their eyes have given way. Now they cannot read for ten minutes without pain and headache.

With a great many of these students the continuous use of a 0.25 cylinder, usually a concave lens, set horizontally, will promptly restore all suspended privileges, and in a very few days enable full work to be resumed. Experience also teaches the wearer of these spectacles, that as long as hard work is continued these glasses cannot be dispensed with, even for a moment, without the return of eye and head pains.

It is very interesting to witness how rapidly the reflex irritations subside, when the irregular movements of the accommodating muscles are no longer called into play. Persons who could not look out into the sunshine before the consultation, find the weak cylinders and their restfulness more comfortable than the smoked glasses which they had been wearing.

It is also an experiment of very great interest in such small degrees of astigmatism as 0.25 cylinder will correct, the more especially if the angle of the fault be an oblique meridian, to note how the reversing of the lens, say from 30° to 150° , will

instantly bring on eye pains and head confusions, and they become so uncomfortable that the patient cannot stand them. Then note the expressions of satisfaction when the lenses are replaced in their proper position. This experiment alone will attest the influence which the very weak cylinders exercise towards the comforting of aching eyes and heads. Even during the office consultation a difference is felt in loss of comfort as soon as the cylinder glasses are removed from the eyes.

I find myself frequently discarding + spherical glasses given for the correction of muscular accommodative astheropia, because with $V. = \frac{2}{3}^\circ$ the true cause of the painful eyes and head aches, which had continued, notwithstanding the use of the + s., *a low degree of astigmatism*, had not been found out, or had not been considered worthy of recognition by the specialist who preceded me in the treatment of the case.

I also find myself frequently substituting the 0.25 cylinder for the 0.5, which is the weakest lens that many ophthalmic surgeons prescribe. Patients who cannot use their eyes for even a few minutes with the 0.5 — c., can read by the hour with the 0.25 c. When these patients are examined by the clock dial lines they will promptly discard the 0.5 in favor of the 0.25 in the uniform coloring of the lines.

Knowing by my every day experience, the value of the 0.25 cylinder lenses, also the great annoyance which this low degree of astigmatism produces under eye pressure, and being therefore constantly on the lookout for it, I can nearly formulate this proposition. Patients with $V. = \frac{2}{3}^\circ$, reading readily the finest print, with distant vision not much improved by + or — glasses, persons who cannot use their eyes for near work without pain, will be found on careful examination to have a low degree of astigmatism which a 0.25 cylinder will correct, to their very great comfort.

Often in testing these eyes which pain on use, they seem to possess perfect vision. In many the astigmatic dial will appear correct, all the lines seeming to be of uniform blackness. These are the patients to whom + spherical glasses are given by many ophthalmic surgeons, because the examination is deemed complete, and the low degree of astigmatism has not been detected. Put a 0.25 spherical lens before one eye, the other being closed, and the difference in the coloring of the lines will at once become prominent. *The latent, but painful astigmatism, becomes apparent.*

It is very important in the detection of these low degrees of astigmatism to close one eye. At times I find the error of refraction in one eye at right angles to the faulty meridian of the other. With both eyes open the clock dial lines are perfect, each eye seemingly correcting the fault of the other. Should the patient be examined with

the two eyes directed to the astigmatic lines the cause of painful vision would remain unnoticed. It is only when one eye is closed that the fault becomes recognizable.

Even with the one eye the sharpness of outlines of the radiating lines will vary. First one, then another, seems better outlined as the ciliary muscle modifies the crystalline lens surface in its attempt at overcoming the fault in the cornea. After staring at the dial for some little time the true meridian fixes the best lines. The faulty lines do not always come out in gray, contrasting with the sharply cut black ones. Sometimes they appear as bright blue or red, and startle the patient by the contrast.

In correcting these weak degrees of astigmatism I find the use of atropia very misleading. Hence, as a rule, I do not use it in determining the kind, and the direction of the faulty focusing in cases of $V. = \frac{2}{3}^{\circ}$, unless glasses prescribed without the use of atropia, do not give the desired or expected comfort. When I speak of atropia I mean homatropia, which I have exclusively used for many years for refractive work. With very few exceptions the mydriatic reverses the kind and the direction of the faulty meridian. An astigmatism of 0.25 — c. o. becomes under atropia 0.25 + c. 90. In the majority of patients the reversed lens + c. does not give the degree of comfort in its use that the — c. will, the one which corresponded with the normal condition of the eye, before the atropia was used. I find these low degrees of astigmatism, as modified by atropia, a fictitious condition which will most frequently mislead the surgeon who accepts it. Should there be any doubt in the mind of the patient as to the exact angle of the fault, then atropia lends a valuable aid in determining it.

As this, however, is not intended for a paper on astigmatism, an important error of refraction, but is designed to call attention to the necessity of correcting the minor degrees of irregular refraction in patients who have $V. = \frac{2}{3}^{\circ}$, a condition which many ophthalmic surgeons ignore, my object can be best illustrated by giving a synopsis of my individual office work for 1888. This list refers to private practice only, and does not include the many cases of astigmatism, worked out by my assistants at the Presbyterian Eye and Ear Charity Hospital where my dispensary work is done. In my office case-book for the year 1887, I have recorded the history of 493 persons for whom I have prescribed cylinder glasses. As in many of these persons each eye differed both as to the kind, the degree and the angle of the irregular refraction, I have thought it best in tabulating my astigmatic work, to refer to the 986 eyes rather than to the 493 persons. All of these patients sought advice for the relief of eyes which were painful on use. I used atropia on 135 of the 493 persons, in about 27 per cent. of the

cases. These were pay patients who expected relief. Had the glasses prescribed not given comfort, they would have returned for further treatment, and I would then have used atropia to sustain, correct, or to modify my first diagnosis. I must therefore believe that the majority of the glasses prescribed, without the use of homatropia instillations, were satisfactory. In a great many instances I have evidence of the entire comfort secured, and the perfect control regained over the eyes even months after the glasses 0.25 — c. were given.

TABLE Showing the Direction of the Error of Refraction.

TABLE Showing the Degree of Astigmatism in 986 Eyes Prescribed for in the Office Practice of Dr. J. J. Chisholm, of Baltimore, Md., during the year 1887.

Of the 986 eyes, all of them more or less painful in use, so that relief was sought, 546 indicated an error of refraction which a 0.25 — cylinder corrected. Had I not sought for, and

found this small error, which in the relief given proved to be the cause of all discomfort, I would have turned away nearly two-thirds of my patients unrelieved. Some of these patients brought painful eyes and 0.5 cylinders prescribed by ophthalmic surgeons of deservedly high standing. The change from the 0.5 + or — cylinder lens which over corrected, to the 0.25 cylinder which made the lines on the dial uniform, removed at once the discomfort complained of. It enabled patients to read by the hour when with the stronger glasses they could not use their eyes at all. This magical and immediate change was brought about by no other treatment than the recognition of the low degree of astigmatism, and the substitution of 0.25 for 0.5 cylinder. In some cases of defective vision sight would be improved from $\frac{1}{30}$ to $\frac{1}{15}$ by these weak cylinders.

As I have been pursuing this line of investigation for several years, and have learned to suspect low degrees of astigmatism in eyes painful in use, which exhibited $V. = \frac{2}{30}$, in seeking for it I find it. I could readily, from my case-book, give the detailed account of hundreds of patients, who, from not being able to read for more than a few minutes without glasses, could by the aid of a 0.25 cylinder, read for many hours.

It is only necessary to call attention to the frequency, and to the annoyance of these small degrees of astigmatism to have others find them as frequently as I do. The more familiar one becomes with these minor defects the more readily are they detected. I am sure that every month's experience adds to my facility, and also to the number of cases seeking advice. For the year 1887, 546 painful eyes showing only 0.25 D. fault were prescribed for in my private practice, and were relieved.

Through this paper I desire to impress others with my conviction, that painful eyes with $V. = \frac{2}{30}$ very frequently means astigmatism. Also that experience will show, that the most useful cylinder for the correction of eye and head pains in this very large number of patients, is the 0.25 D. cylinder. From my standpoint it becomes the most valuable astigmatic lens of the Trial Case.

DR. H. CULBERTSON: As to the 0.25 diopter being the more useful of lenses in the correction of ametropia, I can verify Dr. Chisholm's position to the letter. Not infrequently I can double vision with a D. 0.25 + or negative. As to the correction of ametropia upon the apparent refraction of an eye, I would say that I have not infrequently been compelled to do this after having used mydriatics and when the latter denoted the employment of different glasses.

As to binocular astigmatism, I must assure the Section, and especially Dr. Savage, that my views are original on this subject, and that I had not seen his article on this theme until he kindly pre-

sented me with a copy since I read my paper before the session. The doctor and myself have both been engaged in investigating this form of ametropia for about the same length of time and independently and unknown to each other.

Being a devotee to truth and not wedded to any solution of the *modus operandi* of binocular astigmatism, or claiming in my paper more than a hypothesis as to the cause of this anomaly, I can only learn with pleasure of the views of Dr. Savage. In looking over his brochure on this subject hastily I understand that gentleman to hold that the entire phenomena of binocular astigmatism is due to anomalies of the four oblique muscles. If I am correct in this inference, I am compelled to differ on this point, believing that the state of the recti are concerned in this anomaly not infrequently, as well as the oblique. The five-minute rule will not permit me to enlarge upon my views on this point.

As to the relation of the ciliary muscle to this anomaly I cannot now state a positive opinion, for my investigations as yet do not permit me to say that it has not a positive or negative influence in the phenomena of binocular astigmatism. As for myself, future investigations must determine this point.

SOME OF THE INFLUENCES OF THE SYMPATHETIC NERVOUS SYSTEM IN DISEASE.

Read in the Section on Practice of Medicine at the Thirty-ninth Annual Meeting of the American Medical Association, Cincinnati, May, 1888.

BY JOHN NORTH, A.M., M.D., Ph.C., F.S.Sc., LOND.

PROFESSOR OF CHEMISTRY, TOXICOLOGY AND RHINO-LARYNGOLOGY, COLLEGE OF PHYSICIANS AND SURGEONS, KEOKUK, IOWA.

My attention was drawn to the influences of the sympathetic nervous system, in diseases of mucous membrane, in connection with my studies in rhinology and laryngology. In a paper read before the fourth annual meeting of the American Rhinological Association, at St. Louis, in 1886, on "Naso-pharyngeal Catarrh, as a Cause of Neurasthenia," I attempted to show that functional derangement of the different portions of the body were effected through the great sympathetic nervous system. Also, in a paper read before the American Rhinological Association, at Washington, last September, on "The Pathology and Treatment of Naso-pharyngeal Catarrh," in which I attempted to demonstrate that the diseases of the nasal and pharyngeal mucous membrane, generally called naso-pharyngeal catarrh, was not an inflammation of the mucous membrane, but was a condition produced by paresis of the sympathetic ganglia and nerves supplying the mucous membrane and blood-vessels of these parts.

In the last mentioned paper I alluded to the

fact that if paresis of the cerebral and cervical ganglia and nerves of the sympathetic nervous system caused catarrhal and other troubles in the upper air passages, that it might be the means of explaining a great many pathological conditions in organs and portions of the body supplied by the sympathetic nervous system. It is for the purpose of calling attention to the pathological conditions of the sympathetic nervous system, or to the pathological conditions of the parts supplied by this system of nerves, that I present this paper. The term pathology is too frequently used where pathological anatomy should be used. In a large number of troubles produced by paresis of the sympathetic system, we are not able to detect anatomical lesions. Pathology bears the same relation to pathological anatomy that physiology does to histology.

I will not take up your time with the anatomy of this great nervous system, taking it for granted that every member of the American Medical Association is familiar with the anatomy and histology of both the cerebro-spinal and sympathetic nervous systems.

The anatomy, histology, physiology and pathology of the sympathetic nervous system is one of the most interesting and of the greatest importance to every medical man. Yet it is a subject that is very much neglected in our medical colleges and by medical men after they enter practice.

This system of nerves is sometimes called the ganglionic nervous system, and the nervous system of organic, or vegetable life. By a more thorough knowledge of the sympathetic system we might be better able to understand what appears to be some of the mysterious phenomena of disease.

Commencing as it does within the cranium by the ophthalmic ganglia, with its double chain extending down on either side of the spinal column, terminating below in front of the coccyx in a single ganglion—the coccygeal ganglion.

In the cranium we have four ganglia, called the cerebral ganglia, the ophthalmic, the sphenopalatine, the otic, and the sub-maxillary. In the neck there are three cervical ganglia; the superior, middle, and the inferior. In the chest are situated the twelve thoracic ganglia, corresponding to the twelve ribs. In the abdomen we find the great semilunar ganglia, sometimes called the abdominal brain, with its large plexus of nerves, called the celiac plexus. In the lumbar region, in front of the spinal column, are the four or five lumbar ganglia. In the pelvis we have the four or five sacral or pelvic ganglia, and terminating below and in front of the coccyx, is a small single ganglion, the last of the double chain called coccygeal ganglion, or ganglion impar. Thus the sympathetic nervous system, or cord, as it is sometimes called, consists of from twenty-eight to

thirty ganglia on either side of the spinal column, terminating below in a single ganglion. Each ganglion is connected by nerves with the other ganglion of the same portion, each group of ganglia being connected with the group directly above or below. Each ganglion is also connected with the cerebro-spinal nervous system, receiving filaments from the cerebro-spinal afferent nerves and giving off nerves to the cerebro-spinal efferent nerves in addition to the filaments it gives off to the organ or tissue it supplies.

The question has frequently been asked as to the dependence of the cerebro-spinal and sympathetic nervous system upon each other. In a course of lectures recently delivered by Dr. Gaskell, before the Royal Institute of London, he claims that no new nerve fibres arise in the sympathetic ganglia, but that the fibres destined to them from the cord comes from the inner portion of the posterior horns and inner portion of the gray matter. They are medullated, but in passing through the ganglia they lose their medullary sheath and divide into smaller strands. The old distinction between the two nervous systems, that the cerebro-spinal needs repose, whilst the sympathetic does not, since it cannot be proved, and indeed, is highly improbable that the activity of the brain and spinal cord is ever completely in abeyance. Dr. E. Long-Fox, in his excellent work on the sympathetic nervous system, gives a number of instances of the natural dependence of the two systems. He says, "The fact, that in spite of this natural dependence the sympathetic, under conditions of lesions of brain or cord, is enabled within certain limits to act independently." Parks states that nutrition is probably carried on with complete destruction of the cerebro-spinal centres.

Fox states that "reflex irritation of the vasomotor nerves can be entirely limited to the particular organ or tissue supplied." Thus in Vulpian's experiment, some days after the transverse section of the sciatic nerve, or of the brachial plexus, when the corresponding pulp of the paws of the animals had become quite pale and anæmic, he was able by slight rubbing of these pulps to cause a reflex congestion. The fact of the continuance of the heart's action for a time in some mammals after its separation from the body, in the frog, after the destruction of the brain and medulla oblongata, irritation will cause congestion of the limbs. In mammals, after section of the cord at the mid-dorsal region, sensory excitation of one posterior limb will cause reflex heart phenomena in the other.

While the sympathetic ganglia may not, and probably do not, have the power of generating nerve force independently of the cerebro-spinal system for any great length of time they do seem to act as storage batteries and accumulate nerve force generated by the cerebro-spinal system.

This accumulated force is capable of carrying on the life process after the cerebro-spinal system ceases to act. But this action can only be kept up for a limited time unless reinforcement is received from the cerebro-spinal. This reinforcement is received through the afferent filaments going to each ganglion. If a lesion of the cerebro-spinal system takes place in the region of these afferent nerves, or the afferent nerve is severed, the ganglion will only retain its power for a limited time and the same result will take place that is found after the lesion of the ganglia or its nerves.

Fox says, "Lesions of the cervical cord may cause the same oculo-pupillary phenomena as lesions of the superior cervical ganglion." Lesions of the cervical cord (seventh cervical and first dorsal) may cause the same vaso-motor paralysis evidenced by unilateral vascular dilatation of the face, ear, and head, as is seen in lesions of the cervical sympathetic ganglion.

Hemisection of the lower third of the dorsal region of the cord produces vascular dilatation in the lower limit of the corresponding side, and so increase of temperature.

All lesions of the spinal cord, and pressure on it, may enfeeble the vascular tone of the parts in relation by their vaso-motor nerves with the region of the cord below the lesion. The general distribution of the sympathetic nerves is to the mucous membrane, and possibly to integument, to non-striated muscular fibres to the heart, and particularly to the muscular coats of the arteries. The parts principally supplied with sympathetic nerves are usually capable of none but involuntary movements, and when the mind acts on them at all it is only through the strong excitement or depressing influence of some passion, or through some voluntary movement with which the action of the involuntary part are commonly associated. In the volume on the nervous system in "Flint's Physiology of Man," we find a long list of experiments made upon the sympathetic system, for which I am much indebted, as I make use of a number of them.

In 1727 Petit made some experiments upon the cervical portion of the great sympathetic nervous system. His experiments only showed its influence upon the eye, also, that the influence of the sympathetic nerves was propagated from below upwards towards the head, and not from the brain downward, as in the cerebro-spinal system.

In 1816 Depuy removed the superior cervical ganglia in horses with effect of producing infection of the conjunctiva, increase of temperature in the ear, and abundant secretion of sweat upon one side of the head and neck. In one experiment upon the removal of the ganglia on both sides, in a horse already feeble and emaciated, the face and ears became hot and moist. He says that "the consequences of destruction of the ganglia are, contraction of the pupils, redness of the conjunc-

tiva, general emaciation, as well as œdema of the extremities, and a general cutaneous eruption. These experiments show that the sympathetic has an important influence on the circulation, nutrition, calorification and secretion.

In 1851 Bernard repeated the experiments of Petit, dividing the sympathetic in the neck on one side, in rabbits, and noted on the corresponding side of the head and ear increased vascularity and an elevation in temperature amounting to from 70° to 110° F. This condition of increased heat and vascularity continued for several months after division of the nerve. In 1852 Brown-Séquard repeated these experiments and attributed the elevation of temperature directly to an increase in the supply of blood to the parts affected. He made a most important advance in the history of the sympathetic, by demonstrating that its section paralyzed the muscular walls of the arteries, and further, that galvanization of the nerve in the neck caused the vessels to contract. This was the discovery of the vaso-motor nerves.

The experiments of Petit, Bernard, and of Brown-Séquard, were of great value, as they demonstrated that the sympathetic influences the general process of nutrition, and that many of its filaments are distributed to the muscular coat of the blood-vessels. Flint says, "when the sympathetic is divided in the neck the local increase in temperature is always attended with a very great increase in the supply of blood to the side of the head corresponding to the section. The increased temperature is due to a local exaggeration of the nutritive processes apparently dependent directly upon the hyperæmia. There are numerous instances in pathology of local increase in temperature attending increased supply of blood to restricted parts."

If the sympathetic is divided in the neck of a rabbit and both ears are cut off just above the head with a sharp knife the artery on the side on which the sympathetic has been divided will frequently send up a jet of blood to the height of several feet, while on the sound side the jet is always much less forcible, and may not be observed at all.

Analogous phenomena have been observed by section of the sympathetic in other parts of the body. Samuel has noticed an intense hyperæmia of the mucous membrane of the stomach and intestines following extirpation of the celiac-plexus. By comparative experiments it was shown that this did not result from the peritonitis produced by the operation.

When the sympathetic filaments distributed to a gland are divided the supply of blood is very much increased, and an abundant flow of the secretion follows. Dr. Moreau has made a series of observations on the influences of the sympathetic nerves upon secretion of liquid by the intestinal canal, which are particularly interesting in their

bearing upon the sudden occurrence of watery diarrhœa. In these experiments the abdomen was opened in a fasting animal and three loops of intestines, each from four to eight inches long, were isolated by two ligatures. All the nerves going to the middle loop were divided, care being taken not to sever the blood-vessels. The intestines were then replaced and the wound in the abdomen was closed with sutures. The next day the animal was killed. The two loops with the nerves intact were found empty, as is normal in fasting animals, and the mucous membrane was dry, but the loop with the nerves divided was found filled with a clear, alkaline liquid, colorless, or slightly opaline, which precipitated a few flocculi of organic matter on boiling. I will not enter into the details of the function of the sympathetic nervous system. It is well established that it regulates the blood supply, the temperature, the nutrition and secretion. And in the experiments mentioned it has been seen that the destruction or removal of any ganglia, or section of the sympathetic nerves supplying a certain part or organ of the body, alters the circulation, temperature, nutrition, or secretion, or all these, in the part of the body or organ which receives nervous supply from that portion of the sympathetic nervous system. It is thought that the sympathetic has the power both of conducting, transferring, reflecting, and possibly of augmenting or of inhibiting impressions made on it. Near the terminal filaments of the sympathetic nerves there exists numerous ganglionic cells.

The marvelous effects of reflex action in health and disease, in connection with the sympathetic nervous system, is well recognized by every medical man. For coarse stimuli the spinal cord and medulla oblongata are the chief centres for vasomotor reflex action. But the heart is more or less independent of these great nerve centres. A reflex arc exists in its own substance. Reflex movements are excited from all sensory nerves, not only spinal, but also sympathetic. Claude Bernard has shown that reflex action can occur in the sub-maxillary gland when all nerves that communicate with the cerebro-spinal centre are cut. If the superior cervical ganglia are separated from the higher nervous centres oculo-pupillary phenomena can be reflexly excited. That the uterine centres can act independently is seen in the occasional expulsion of the child after the death of the mother. The expulsion of feces *per anum* after the death of the patient shows also that the sympathetic ganglia of the intestines are centres for independent reflex acts.

In a paper read by Dr. Woakes before the International Medical Congress, at London, he speaks of the sympathetic ganglia as reflex centres. Drs. Fox and Woakes give a number of examples to show the reflex power residing within the sympathetic system.

It is not my object in this paper to call attention to the reflex phenomena of the sympathetic system, but apply the physiological facts we have mentioned to the influence of this system of nerves upon the circulation of the blood and the condition of the blood-vessels, more particularly to that condition called catarrh, or inflammation of mucous membrane, and to the deranged function of certain organs dependent upon disturbance of local circulation. It is impossible to give a definition of inflammation that will be brief and exact at the same time. Inflammation is a term implying a whole series of processes, partly vascular, and partly textural, and their processes admit of great varieties of combinations. We have certain characteristics of inflammation but the whole content of the term cannot be fully indicated without describing briefly the process to which the term is applied. Four cardinal symptoms of inflammation are well recognized, namely: *redness, swelling, pain and heat*, with impaired function. The *redness* is from increased afflux of blood to the part. The *swelling* to an increased volume of blood in the part, and from exudation. The *pain* is caused by the swollen condition of the parts, which cause pressure upon the sensory nerve filament, or by chemical irritation. The *heat* comes from the excessive flow of blood through the part in the stage of hyperæmia.

In inflammation we have both vascular and textural changes. The first vascular change is produced by some *irritant* which being applied there is a general dilatation of the vessels, first of the arteries, then of the capillaries and veins. The flow of blood through the widened channels is more rapid at first. This is the stage of hyperæmia. After a time the speed diminishes, and at length the flow becomes slower than in the normal condition. This constitutes the stage of congestion. During this stage we have a migration of the blood corpuscles through the walls of the veins and capillaries into the surrounding tissue, but not from the arteries associated with the passage of the corpuscles. There is always an escape of liquid, which is comparatively rich in albumen. This is the stage of exudation, or infiltration.

All these changes and stages depend upon a molecular alteration in the walls of the blood-vessels. Mere paralytic dilation does not give rise to slowing of the current or to the passage of the blood corpuscles through the walls of the vessels. The inflammatory changes in the blood-vessels must of necessity be associated with tissue changes. These changes vary with the nature of the exciting cause, and with the intensity of the inflammation, with the character and extent of the vascular disturbance, and with the nature of the tissue. Inflammation cannot exist without molecular death.

Is it possible to have these cardinal symptoms of inflammation, *redness, swelling, pain and heat*,

with impaired function dependent upon paresis, or paralysis of the sympathetic nervous system, without inflammation, without structural change in the blood-vessels, without molecular death? This question opens up the question of contractions, dilatation, erectility and reflex vaso-motor effects. The function of the vaso-motor nerves most frequently called into exercise is contraction.

Fox says, "The motor nerves that preside over the muscular contraction of vessels, and rule the local circulation, are the nerves that issue mainly from the ganglia of the great sympathetic, creep along the arterial walls, and can be followed into the middle muscular coat of the arteries. The vaso-motor apparatus therefore is in a state of permanent activity, never in repose, never inert. The muscular tunic of the vessels is in a state of semi-contraction—in other words, of vascular tone. Variation in this tone will be the necessary consequence of various modifications of the nervous apparatus."

The vaso-dilators are also in a constant state of action but are fewer in number than the contractors. Were it not for the pressure and action of the vaso-dilators, the vaso-contractors would cause undue and complete contraction of the vessels. The arteries possess both elasticity and contractility; the small arterialis contractility only. The vaso-contractors and dilators acting together keep up the proper calibre of the vessels.

When from the presence of some irritant upon the vaso-motor nerves, or as the result of mental impressions, etc., by reflex action, the vaso-motor nerves become affected, lose their tone, the ganglia soon loses its power, paresis, or partial loss of power takes place, the vessels dilate and remain dilated. As the result of this ganglionic paresis, we have *redness* from the increased afflux of blood to the part, we have *swelling* from increased amount of blood in the part, and after some time from the excessive nutrition furnished the tissue, the *pain* being produced by the pressure upon the sensory nerves, the *heat* from the rapid and excessive flow of blood through the part, we do not have changes taking place in the vascular walls. In the experiments made by Petit, Bernard, Brown-Séquard, and others, to which allusion has been made in this paper, it was shown that by removal of the ganglia, or section of its nerve filaments, that the part of the body supplied from that ganglion had an increased flow of blood into and through the part. That there was considerable increase of temperature, *redness* and *swelling* of the part, and, no doubt, *pain*. That there was increased secretion and nutrition.

In conclusion. When we take into consideration the anatomy and distribution of the sympathetic nervous system, together with its physiological functions, and its pathological action under artificial impairment, is it not reasonable to sup-

pose that if a ganglion becomes impaired and loses its power that we might have such conditions taking place that would explain a number of the phenomena occurring in diseases of organs or other parts of the body supplied by the great sympathetic nervous system?

Would it not explain many of the functional brain troubles? of eye, ear and nose, pharyngeal and laryngeal troubles. Pneumonia can be more easily explained in this way than in any other. Some heart, stomach, and kidney troubles can be explained by sympathetic paresis. Gynecological troubles lose half their terror when viewed from this light.

We all are aware that in the cases of troubles mentioned recovery is more rapid and complete when treatment is directed to the sympathetic nervous system.

A PLEA FOR THE BETTER RECOGNITION OF THE OCULIST IN THE SERVICE OF THE U. S. PENSION DEPARTMENT.

Read in the Section on Ophthalmology, Otology and Laryngology, at the Thirty-Ninth Annual Meeting of the American Medical Association, May, 1888.

BY JOHN W. WRIGHT, M.D.,
OF COLUMBUS, OHIO.

The U. S. Pension Department has been established for the purpose of remunerating those who have become disabled while in the service of their country by reason of injury, sickness or deprivation.

While the Government is endeavoring to provide for these persons, it becomes necessary to guard against impostors, for the recompense is amply adequate to induce those who are so disposed to make the effort to obtain it. For this reason boards of examining surgeons and special agencies have been established throughout the country, as well to enable the deserving to procure what is justly due them as to prevent others from obtaining that which does not belong to them.

At present the applications for this beneficence are in great profusion, for the reason, perhaps, that many of the older ones who served in the late civil war mistake their physical impairments from age for disabilities from wounds and exposures from army life; while others who received injuries while in service or suffered from the sicknesses and privations consequent to a camp life, although not considered at the onset sufficiently disabled for a pension, have developed with increasing years diseases and infirmities which have rendered them confirmed invalids.

It is doubtless the design of the Government authorities that the machinery of the Pension Bureau shall be as complete as possible; for the nearer it approaches perfection the more will the

chances for fraud be diminished, hence every application receives the most careful and deliberate consideration at the hands of this department.

The Medical Referee, in his instructions to examining surgeons, states that (Art. 5) "the object of a medical examination is to obtain a full and complete description of the disabilities for which pensions are claimed, and to gain a *clear and distinct idea of the extent to which they disable in the performance of manual labor.*" (Art. 6.) "To this end it is necessary that *every disability existing shall be fully described,*" etc.

Under the heading of "*Diseases of the Eyes,*" (Art. 58) we find: "In all diseases of the eyes involving internal structures the ophthalmoscope must be brought into use, otherwise the examination is of little value."

In closing the instructions the medical examiners are reminded "that the interests involved in pensions are of such magnitude as to demand the employment of the very best skill this country can supply." The term "a full and complete description of the disabilities" is sufficiently significant to indicate the desire of the head of the medical department.

That "the ophthalmoscope must be brought into use, otherwise the examination is of little importance," is pertinent; but could the department have fully comprehended the necessary knowledge of optical principles and the constant and unremitting practice which underlie a correct application of this instrument, in order to be able to detect the various pathological conditions in eye affections, I do not believe this last clause of instructions would have been imposed upon medical gentlemen of whom not one in every hundred can realize the practical value of this instrument. This may seem to many an exaggeration, yet I believe every oculist here will bear me out in this assertion. Nor is this intended to reflect upon the abilities of examining surgeons—for there is not an instrument of diagnosis of such incalculable value, in my estimation, so difficult of application as the ophthalmoscope.

In making this entreaty, a few cases which have come under my immediate observation may be in place.

A gentleman living in the eastern part of Ohio, who served his country during the War, made an application for a pension because of a disease of the eyes which rendered him almost blind and incapable of earning a livelihood.

He was ordered before a board of examiners, and in due time he received a pension and considerable back pay. Some time afterward he was induced by his friends to consult me in reference to his eyes. I found that he had entropion, which had followed what he termed the "army sore eyes." There was no complication or structural disorganization of the parts, the inflammation being simply mechanical, the result of the hairs

which were constantly rubbing against the balls.

I informed him what could probably be done and, seeing an opportunity of giving him great relief, I encouraged him with the possibility of considerable improvement in his vision. I saw that he was not favorably impressed with my opinion, and I naturally presumed that he did not have the confidence in my ability to accomplish that which I had given him encouragement could likely be done. I afterward learned that he had *too much* confidence in my ability to help him. He feared that the operation would prove so successful that he would be compelled to relinquish his pension. Afterward, upon making inquiry, I was surprised to learn that he had obtained his pension because of "glaucoma."

Mr. B. had served considerable time in the army. Four years ago I operated upon one of his eyes for cataract, he being blind in both eyes. The operation proved very successful and the patient returned to his former occupation—that of a contractor—which he had been compelled to relinquish almost a year before the operation, and which he now manages with very little inconvenience.

Not long since he got into the hands of a pension solicitor and was easily made to believe that his blindness had been the result of sickness and exposure while he was in the service. He "*did*" remember of having had the jaundice while in camp," and how "*yellow*" his eyes looked. "This was doubtless the key to his blindness."

An application for a pension was at once made, and in due course of time he was ordered to appear before the board of examining surgeons. One of the examiners who makes some pretensions to a knowledge of eye diseases and the use of the ophthalmoscope was delegated to examine all such applicants, and accordingly examined this gentleman's eyes.

An elaborate examination was at once commenced, and the ophthalmoscope was brought into vigorous use. An hour at least was consumed in the examination. Of course the opaque lens was seen in the eye which had not been operated upon, or I presume it was, as the ophthalmoscope was made to play upon it at least one-half of the time; and in the other eye the cicatrix where the incision had been made in the upper part of the cornea, and the irregular-shaped pupil, were plainly discernible, and excited the interest of the surgeon.

The surgeon inquired what had happened to the eye. Evasively he was answered that "some doctor had been trying to operate upon it." The examining surgeon then ventured the remark that it had been "*badly butchered,*" and advised him not to allow the other eye to be "meddled with," or he would be left "*entirely blind.*" The applicant has received, I understand, a comfortable pension.

Of course it is impossible for us to say that the applicant's jaundice, together with his other sicknesses and exposures in the service, *did not* cause or contribute in some way to the opaque condition of his lenses, although his mother and a sister, who were not exposed to these influences, were both blind from cataract.

Although the origin of a disability is considered a legal matter; that is, a thing to be determined by evidence obtained outside of the medical examination, yet the examining boards are largely entrusted with the duty of distinguishing and separating disabilities of origin either before or after enlistment from those which occurred during the actual service.

In the above case the opinion of any reputable oculist, doubtless, would have precluded a pension.

A gentleman from the southern part of Ohio came to my office a few years ago and desired me to make an examination of his eyes and give him a written opinion. He made the statement that while in the army he had had sunstroke, and with it the loss of an eye. He was discharged and sent home, not on account of the loss of the eye, but because of his general physical disability which followed the sunstroke.

A few months after returning home, while engaged in some work requiring physical exertion, he suddenly lost his sight in the other eye. He was now practically blind, although not *entirely* so, for he could grope his way around to a better advantage than if he had been totally blind, but he was so blind that it was impossible for him to distinguish one object from another, or to be able to perform any labor that could not have been accomplished by a blind man. He had made several attempts to procure a pension, and had been ordered before different examining boards; but for some unaccountable reason to him he had never been able to obtain it. Finally it came to his ears that it was intimated by some persons that he was a malingerer, and it was to contradict this report and to place himself in a proper standing among his friends, rather than an aid in procuring the pension, that he desired the examination and a written statement concerning the condition of his eyes.

The examination with the ophthalmoscope revealed the fact that there had undoubtedly been very extensive retinal hæmorrhages involving the maculæ in both eyes. The hæmorrhagic spots had been unquestionably very numerous, as there were many places marked by choroidal alteration or replaced with blackish pigment. In other places the retinal tissue seemed to be degenerated and marked by a whitish or grayish tinge. There was such complete destruction of the retinal tissue that it was impossible for him to more than know that an object was in front of him in good light. I gave him a certificate stating the facts, since which time I have heard nothing from him.

I do not recollect of ever having seen or heard of retinal hæmorrhage caused from sunstroke, but, owing to the engorged condition of the sinuses and veins of the brain during the active stage of the affection, it is readily understood how it could occur.

The second hæmorrhagic attack can be explained because of the tendency of recurrences of cerebral engorgement after sunstroke, marked by sudden depressions upon exposure to heat or bodily exercise.

It is fair to presume that the surgeons who had examined him took into consideration the external appearances of his eyes, and had overlooked their retinal condition.

As oculists are generally aurists, the following case which refers to the hearing is permissible:

A young man enlisted at the beginning of the War and was in active service most all the time until its close. He was in many engagements where there was heavy cannonading. When he was discharged he was somewhat deaf, and grew gradually worse for ten years following, at which time it was almost impossible for him to understand the loudest talking. Since that time he has remained in this condition.

About eight years ago I saw him, when he was making an effort to obtain a pension. He came to me because I had known him before he entered the service, and also because, he said, he had consulted me in reference to his deafness immediately after his return from the army. I have, however, no record or remembrance of his consulting me at the time mentioned by him, but from an incident which he referred to as having occurred at the time, I presume he did. At any rate I was not able to testify, as he desired evidence to establish the time the deafness began and its continuance, in order to associate it with the exposure to the heavy cannonading during the service.

Having no record of the examination I made eight years ago, I am not prepared to give the details, yet I am confident I found no appreciable lesion, because of an opinion I formed of his case at the time, and which I have had in my mind ever since, relative to the cause of his deafness.

I came to the conclusion that there was an ankylosis of the joints of the bones of his ears. These bones, as we all know, are, or should be, freely movable at their joints, although delicately attached to each other. Their articulating surfaces are covered with cartilage and connected with capsular ligaments, and lined with synovial membrane, the same as the articulating surfaces of other bones, and are no doubt liable to the same diseases as the larger joints. These joints are so adapted as to allow of the motions of the bones conveyed to them through the membrana tympani from ordinary sounds, and they perform their functions perfectly well and without injury to themselves under these conditions. But heavy

cannonading would cause, through this membrane, excessive action of these joints. Then why is not a synovitis just as likely to be induced here as it would be in the larger joints, where it is so liable to end in an ankylosis?

But it matters not whether the deafness is caused from an ankylosis of the bones of the ear or, as some authors would have it, in case of boiler-makers and others subject to like noises, that it is due to nervous exhaustion from continued shock, or, as explained by others, from chronic catarrh of the middle ear; it is quite sufficient for us to know that cannonading has been the cause of very much and intense deafness.

In this case it is impossible, perhaps, to establish an unbroken chain of evidence from the time of the inception of the injury until very marked deafness ensued, from the very fact that slight deafness, or what is termed dullness of hearing, is not very noticeable except to one's most intimate friends or associates. When the patient is no longer able to distinguish ordinary sounds, then it is noticeable to all.

Evidence that this man was exposed to heavy cannonading during his service, and that the deafness now exists—in the absence of lesions that would indicate that the deafness was not the result of army exposure—would be sufficient grounds for allowing him a pension.

If, as expressed by the Medical Referee, "the interests involved in pensions are of such magnitude as to demand the employment of the very best skill the country can supply," then it is nothing but just that *all* applicants claiming defect in sight or hearing should be referred to boards of examiners composed solely of experts in this particular class of affections.

The number of applicants claiming defect in vision alone would justify this. From July, 1886, to December, 1887, there were 4,672 pensions granted for disabilities of the eyes. As about 12 per cent. of all applicants during this time received pensions, then there was the enormous number of 39,000 applications in this class alone.

In concluding this argument I disclaim any selfish motives more than a desire that our profession may be the means of promoting the interests of many worthy applicants, and of increasing the efficiency of the Pension Department by contributing the very best skill for the examination of this particular class of applicants.

OXYPIPERIDIN, a substance derived from the distillation of benzolamidovalerianic acid, is very similar to strychnine in its action, being a strong tetanizer. The crystals of oxypiperidin melt at 30°-40° C. They are soluble in water, alcohol, ether and dilute acids. When oxypiperidin is boiled with strong acids the non-toxic substance α -amidovalerianic acid is formed.

A CASE OF PLACENTA PRÆVIA.

Read before the Medical Society of the District of Columbia, April 25, 1888.

BY PHILIP MARVEL, M.D.,
OF WASHINGTON, D. C.

The subject of this report, Mrs. S., was a colored woman *æt.* 38, of medium height, small in stature, much reduced and emaciated by phthisis pulmonalis; married, one child 13 years old; no miscarriages, and had been in expectancy for some seven months when seen first by me.

According to her own statement, she had been ill of phthisis about two years, the physical signs of which were quite advanced. Through the kindness of Dr. Muncester, who was attending her at the time for a slight uterine hæmorrhage, I was asked to take charge of her case. A second hæmorrhage occurred some three weeks later, though of little consequence so far as related to the quantity of blood lost.

My suspicion at once was that I had to deal with a case of placenta prævia, though an examination added little to strengthen or verify such a suspicion. The mouth of the womb was well closed, and quite impossible for me to insinuate my finger sufficiently far, within the cervix, to ascertain a placental offering without forcing dilatation, the expediency of which I shall have more to say further on. Principally rest, with little medication, was quite sufficient to check the flow, and my attention was then directed to the upbuilding of her general condition. Nutritious foods, good air, bromine and dilute phosphoric acid constituted the principal means employed. These were apparently effecting the results I had desired, and while waiting an opportune time to induce labor, I was called to see her with another hæmorrhage. Though not profuse, it was alarming, owing to the prostration it occasioned. For some time after my arrival, the hæmorrhage having been checked, she was unable to converse, and only slowly rallied under careful administration of stimulants and artificial heat. At this time there was no longer a question as to the condition, but a grave one, as to the most expedient procedure. To attempt a speedy delivery would be to employ means positively dangerous, and possibly to destroy the little chance that remained for her recovery. I packed the vagina, having previously inserted within the cervical canal a pledget of cotton, and gave my attention to the effort to restore her from the effect of the shock—the result of which was so transitory and unsatisfactory, that it was evident neither a conservative nor radical course of procedure was without danger.

Dr. Reyburn was now asked to see her with me, and found her substantially as above described. I attempted forcible dilatation with the fingers, but found her strength insufficient to bear it, and again we resorted to the tampon and waited dilatation, watching her all the time, and employing such

measures as the case and circumstances would allow. After six hours of watching and waiting, the cervix having in the meantime dilated, we administered chloroform and turned. The feet were brought down, and in ordinary cases, we would have waited for uterine pain and contractions, but in hers, there having been an absolute absence of both from the first, and ergot was without effect in producing them, we considered it hazardous to longer wait, hence proceeded to deliver by accoucheur force. The child being large in proportion to the woman's pelvis, in the absence of maternal aid we found it difficult and slow to relieve her; however, after some time and effort we succeeded in delivering her of a still-born child. The afterbirth soon followed. Uterine contraction was prompt and firm, and no hæmorrhage followed.

Mrs. S. rallied sufficiently to recognize and speak with her husband, nurse, and a friend who stood by her bedside, but shortly began to sink, and thus continued an uninterrupted failure for about three-quarters of an hour, when she expired. All means at hand, such as hypodermics of whisky, atropine, strychnia and aq. ammonia, together with artificial heat, were of no avail.

It may occur to some of you that it might have been wisest, as well as in keeping with a great deal of teaching upon this subject, for me to have induced labor when first I saw her with second hæmorrhage. There are conditions, individual and circumstantial, which should modify our plans and methods of treatment, irrespective, I think, of the fact that some writers have said, in every case of pregnancy when hæmorrhage occurs after the sixth month, premature labor should be induced. While, doubtless, this may serve the end well in many cases, I am strongly inclined to look upon this latter statement as dangerous teaching. Since it is impossible for one to formulate a rule, or set of principles, which will cover all conceivable conditions, it seems both unwise and unwarrantable to ask one to follow absolutely teachings which admit of no qualification. It would seem to conserve the proper end of treatment in any case to use at all times, and under all circumstances, the means which offer the greatest security to life, with the least possible danger. This principle I endeavored to apply to the case before you. When called to see her there was much more to be considered than the question of delivery. This was of little moment compared with the probable results of interference. It was evident to me that she was in no condition to stand the shock which induced labor would in her case occasion, hence the reason why I adopted a conservative procedure, when to prolong gestation was to prolong a threatening danger. The necessity for rapid delivery when induced in this case is, I think, apparent to all, and need not be further referred to. I submit the report to you, and will receive kindly any just criticisms you may have to make.

HYDATIDIFORM MOLE.

*Read before the Medical Society of the District of Columbia,
April 25, 1888.*

BY J. H. MUNDELL, M.D.,
OF WASHINGTON, D. C.

I was called about 11 A.M. on the 12th of April, 1888, to see Mrs. L. T., 19 years of age. Upon reaching the patient's house I was told that she had menstruated last about the 15th day of January. About the first of March she began to suffer with nausea and vomiting. After March 16 the nausea and vomiting became more distressing, accompanied by frequent slight hæmorrhages. A physician was called in, who visited her several times in the next two or three weeks. His remedies failed to give her the slightest relief, and not having made a diagnosis in the case satisfactory either to himself, the patient or her family, he was requested to discontinue his visits. I found her suffering with acute labor pains and flooding very profusely. Upon placing my hand upon her abdomen I found the uterus reaching to the umbilicus, quite hard and of symmetrical shape. A vaginal examination revealed the os uteri dilated just about large enough to admit the introduction of an ordinary sized goose-quill.

Her pulse was very feeble and rapid; indeed, she was almost in a state of syncope. Seeing that miscarriage was inevitable, I immediately proceeded to tampon the vagina carefully and thoroughly, which had the effect of arresting the hæmorrhage for a time. I returned again in about an hour and found that the blood had penetrated the tampon, and a slight hæmorrhage still kept up. I then packed tightly the vagina with as much cotton as I could introduce, and confined it with a T bandage. This had the desired effect of stopping the flow. I had before ordered her to be perfectly still, with her head low, and to eat freely of crushed ice. I visited her again at 6 P.M. and found no hæmorrhage. Upon removing the tampon I found in the vagina, and partially protruding from the os, a large mass of hydatidiform bodies.

By introducing my finger into the womb I scooped out all of the mass I could reach, in quantity about a quart (which I here exhibit, except a portion which was lost by adhering to the bed clothes).

The patient then seemed so very weak and the uterus so extremely sensitive and tender, I desisted from making any further exploration, believing, also, that I had secured about all of its contents. After giving ergot as a precautionary measure, and enjoining perfect quiet and recumbency, I left her for the night. The next day I found she had passed a rather sleepless night; her pulse was 120 and very weak, and her temperature 101°. I ordered warm carbolized vaginal injections, and full doses of quinine with

opium, to procure sleep. She was given also milk, beef-tea and milk punch. On the third day her temperature was 99° and pulse about 112. From that time to the present she has steadily improved, and is now able to sit up, although still very pale and anæmic; has a good appetite, and is taking quinine and iron.

Another form of hydatidiform pregnancy is what is called the fleshy mole, also called the true mole in contradistinction from the false mole, which occurs without impregnation.

About twelve years ago Mrs. T., then about 30 years of age, came to consult me at my office. She was looking very pale and anæmic. She complained of great debility, loss of appetite, and inability to make any exertion or attend to her household duties. She further stated that she had not menstruated for five months. I examined her uterus, but could find no appreciable change or enlargement to indicate pregnancy. Her lungs showed no evidence of phthisis. I put her upon the use of iron, quinine and strychnia, with as much nourishing food as she could take. She improved rapidly. After visiting me at my office several times, each time expressing herself as feeling much better and gaining strength, she changed her place of residence and stopped coming. I thus lost sight of her for about five months, when one afternoon I received a summons to come to her immediately, as she was very ill. When I got there she stated that shortly before sending for me she had been seized suddenly with violent pains in her back and lower portion of her abdomen, accompanied with some discharge of blood, which alarmed her very much, but that soon after dispatching her messenger she was relieved, after passing something hard and solid through the vagina, which, upon inspection, proved to be a fleshy mole of the shape but rather larger in size than a hen's egg. She then informed me for the first time that some three years previous, whilst under the care of the late Dr. Benjamin Thompson, of this city, she had passed a similar lump of flesh.

In this instance she had not menstruated for about nine months, four months before she first came to my office, and five from that time to the day when I visited her at her house.

Our much respected President, Dr. Thomas C. Smith, on the 23d of September last reported to this Society two cases of hydatidiform moles similar to mine, and at the same time so thoroughly discussed in his paper all of the literature relating to the causes and formation of these productions, that I deem it unnecessary for me to occupy the time of the Society by saying anything more on this subject.

THE AMBULANCE TENTS AND WAGONS of Captain Tompkins received the diploma of honor at the Brussels Exhibition.

REPAIR OF A RUPTURED CHORION. REPORT OF A CASE.

BY W. L. SCHENCK, M.D.,
OF OSAGE CITY, KAN.

On the first day of June, 1888, I was called to see Mrs. James L., living six miles south of the city. She had been thrown from a heavy farm wagon which, turning over, struck her across the lower portion of the abdomen and hips with such force that she was unable to move her body or lower limbs for several weeks. She was seven months advanced in her sixth pregnancy. Active uterine pains came upon the second day after the injury, the membranes rupturing on the third with a free discharge of liquor amnii. Despite hypodermic injections of sulph. morph. and atropia, rectal enemata of tinct. opii, etc., the os dilated and the pains and discharge continued for three days, the pains steadily growing less forcible and the waters less abundant, when both ceased and there was gradual improvement in the general condition, but any attempt to walk was accompanied by a free movement of the pubic bones at their symphysis and severe pain in the right side and hip, and she maintained an almost immovable decubitus.

On the 4th of August, at the end of her 280 days, I was again summoned to the patient's bedside. The labor progressed rapidly, the membranes rupturing early, and on reaching the house a healthy boy of 9 pounds awaited my arrival. I removed the secundines, which were buttonholed in the vagina, and carefully examined them. The rent in the chorion through which the child had escaped was near its centre. About midway between this and its attachment to the placenta there was a triangular fold in the membrane (which is very prettily preserved in alcohol), that had united by adhesive inflammation. The chorion was separated from the amnion throughout one-fourth its extent, the inner membrane being thickened and presenting on its outer surface—in the vitriform body—an ecchymosed appearance, the spots of blood varying in size from a pin-point to $\frac{1}{8}$ inch in diameter, and being covered with a delicate film of membrane.

Though this case is unique, not having found in my reading a similar one, its possibilities are readily appreciated. There was a rent—solution of continuity—in a serous membrane, which was folded together and held by the parts adjoining so as to close the opening; there was consequent irritation and exudation, and a forced rest that permitted adhesive inflammation—a result that might more frequently obtain after such accidents if we could secure perfect immobility of the parts.

The injury to the mother in this case secured a fixed decubitus. The lesson to be learned from it is a more positive insistence upon perfect rest. We know not in what case we may have a fortunate folding and pressure of the membranes which, if

maintained, may be followed by adhesion and a successful termination of the pregnancy. Not only must *absolute* rest be enforced until there has been sufficient time for union by adhesive inflammation, but a reasonable quiet must be maintained until after delivery.

MEDICAL PROGRESS.

REGULATION OF FLUID INGESTA IN CARDIAC FAILURE.—In a paper on this subject DR. J. BARR says:

Some time ago I had a patient who suffered occasionally from irritation of the urinary passages, with excessive excretions at times of uric acid, and at others of earthy phosphates. It was a case where the use of mineral waters might seem to have been indicated, but, as he had a feeble circulation, I cautioned him, before his visits in two successive years to two celebrated mineral water resorts, to be satisfied with the pure air and healthful exercise to be obtained in those elevated regions, without trying their supposed marvellous springs. On both occasions he was induced to consult a leading physician in each place, who understood all about the wonderful virtues of the waters, with the inevitable result that the waters were freely prescribed. On each occasion the patient returned much worse than when he left, and was afterwards quickly cured by a quinine tonic, and increased oxidation by healthful exercise in a place where there was no mineral spring.

I have, at present, under my care in the Northern Hospital, a patient who was admitted some weeks ago suffering from great mitral constriction, free tricuspid, regurgitation with evidence of commencing stenosis, great enlargement and hardness of the liver from chronic congestion, large ascitic effusion, general venous turgescence, and urgent dyspnoea. On a dry diet the patient has markedly improved: there is no dyspnoea, the venous turgescence has disappeared, the ascites has lessened, and she is now able to move about the ward, and has the prospect of returning home fit for light household duties. This woman has been several times in another institution, where she was kept on a liquid diet, and as she thought that an excessively morbid interest was taken in her case, on each occasion when she considered that she was near her latter end, she fled home to save a post-mortem examination.

Every drop of liquid which is placed in the stomach, with the exception of part of that which passes away in the faeces, must pass through the right side of the heart, and all of this, except that which is exhaled by the lungs, must pass through the left side before it can be excreted. When, therefore, there is any mechanical obstruction to the passage of the blood through the

heart, or, when the effective force of the heart is diminished, any increase in the amount of fluid in circulation must severely handicap the central pump. The velocity of the blood depends on the effective force of the cardiac contractions, and on the mass to be moved, and is inversely as the sectional areas. It therefore follows that when you have got a weak heart and a great amount of blood in the vessels, the circulation becomes very languid, and in a given time comparatively little is presented to the excretory organs. By the use of cardiac tonics to improve the force of the heart's beat, and by reducing the supply of fluid, thus lessening the bulk of blood, we lessen the static condition, and increase the velocity of the circulation. The potential is converted into kinetic energy, there is a more rapid interchange of fluids between the blood and tissues, the hydration of the tissues is lessened, while the oxygen-carrying power of the blood and the oxidation of effete products are augmented, the congestion of all the internal organs is diminished, and their functional activity heightened.

When there is any marked cardiac failure, the quantity of fluid consumed should be restricted to the smallest possible amount, and, in a large number of cases, one pint of liquid, including the fluid portion of the food, will be found sufficient, while if there be any dropsy, the quantity may, in many cases, be reduced still further.—*Provinc. Med. Jour.*, Aug. 1, 1888.

ALKALIES IN ECZEMA.—DR. FREDERICK PEARSE, acting on the principle that acids applied to an acid-secreting surface and alkalies to an alkaline-secreting surface diminish the respective secretions, has treated a large proportion of cases of eczema for many years by alkaline applications. The method may be termed unphysiological, on the ground that the morbid exudation of the eczematous skin has no parallel with the normal secretion of glands, but his answer for the present must be the results. There is not the slightest doubt that an acid applied to an eczematous surface will irritate and increase the exudation, and he is equally satisfied that alkalies, judiciously applied, will have a contrary effect. Whatever views we may have on the pathology of eczema, the great diversity of methods shows that at present we have no very definite *rationale* of treatment. At the same time he does not argue that alkalies have any specific action. No one who has seen much of eczema can doubt that the associated disorder to which these patients are most subject is that connected with their digestive organs. The internal treatment is therefore undoubtedly of paramount importance. The one thing which appears most successfully to meet this indication is some saline aperient, which produces a "weeping" from the mucous surface of the intestines and also hurries on the contents.

This clinical fact suggests that the cause of eczema lies in some imperfect process of digestion, whereby abnormal chemical compounds are absorbed and, circulating in the blood, irritate especially the skin structures. These compounds are unknown. Not only, however, are saline aperients successful in the treatment of eczema, but alkaline combinations are especially so. The most common prescriptions contain these drugs in endless variety.

This treatment is very successful for adult patients, but it is not nearly so useful in the eczemas of young children. In these cases, however, alkaline external applications are as successful as in those of riper years, if not indeed more so. Whether the fault in adult life lies in deficiency, and that of eczematous children in excess, of secretion of acid gastric juice, is difficult to decide; but the internal administration of alkalies combined with saline aperients, in the eczemas of grown-up people, is that on which the greatest general reliance can be placed. In children, however, an exactly opposite line of treatment will often be found successful. It is especially in scrofulous children and in infants that he has found benefit from the internal administration of hydrochloric acid. These little patients have generally some palpable digestive disturbance. He has frequently found unexpected benefit from the internal administration of nitrohydrochloric acid combined with sulphurous acid, at the same time pursuing the external application of alkalies. These latter may be used as solutions of bicarbonate of sodium (5 or 10 grains to the ounce), sometimes combined with small quantities of glycerine, or as weak solutions of liquor potassæ (10 or 30 drops to the ounce). As a general rule, it may be said that the more acute the eczema, or rather the more copious the exudation, the weaker must be the application. It should be made, whenever possible, continuously.

In chronic cases an alkaline ointment may sometimes be used, such as one containing 10 to 30 grains of bicarbonate of soda to the ounce of vaseline.—*The Practitioner*, October, 1888.

STRONGYLUS PARADOXUS.—M. J. CHATIN recently exhibited before the Paris Académie de Médecine a specimen of this intestinal worm, passed by a butcher, at Oloron, in the department of the Basses-Pyrénées. The patient had been subject for some time to gastro-intestinal disturbances, and had already passed another specimen of the same parasite. *Strongylus paradoxus* is a small round worm; the exhibited specimen measured a little over half an inch. The species was discovered in the lung of a wild boar, by Ebel, at the end of the last century, shortly after Modeer and Bremser discovered in Sweden and Vienna that this *Strongylus* infected the bronchial tubes of domesticated swine. Rayer found

the parasites, in the same anatomical situation, in a pig in the Paris market in 1844; two years later Bellingham discovered the parasite in Ireland. For long, experts have admitted that *Strongylus paradoxus* infests the lungs of swine, causing an affection which was rare till recently. Dr. Cobbold, in 1879, and M. Chatin, in 1881, both showed that swine were becoming more subject to this worm. The former pointed out its danger when a large number of worms collected in the bronchi. In 1850 the wild boars preserved for the Royal hunt, near Berlin, were decimated by this *Strongylus*. M. Chatin notes that no report of the existence of this species in man can be found in medical literature, but the alleged new species, *Strongylus longevaginatus*, found infesting the lungs of a child, aged 6, at Klausenburg, Transylvania, in 1845, is evidently, in M. Chatin's opinion, identical with *Strongylus paradoxus*. Hence, in reality, the latter species has twice been found in man, and on the first occasion it infected the lung and caused death. The worm is very tenacious of life, and its embryo may remain in water, or completely dried up for a year without undergoing any change; yet, if then swallowed by a pig in fodder or drink, will rapidly develop and propagate. M. Chatin believes that in the case of Oloron the parasite was probably swallowed in drinking-water. Since swine are becoming more and more subject to *Strongylus paradoxus*, he thinks that sanitarians must be watchful, lest man should become frequently subject to the ravages of a worm liable, from its favorite habitat, to cause more mischief than can be wrought by *Tenia*, *Oxyuris*, *Lumbricus*, or even the leech-like *Dechmius duodenalis*, which caused anemia amongst the men employed in the St. Gothard Tunnel.—*Brit. Medical Journal*, August 18, 1888.

PAQUELIN CAUTERY IN EPIDIDYMITIS.—According to DR. BREWER, good results are derived from the use of the Paquelin cautery. He has employed this method in forty-six cases, and in two cases only was it necessary for the patient to remain in bed after the first application, and in one the real cause of the enforced rest was a co-existing cystitis. The details of the procedure, according to Dr. Halsted, who first suggested it, are as follows: The cautery point is heated to a white hot temperature, and the surface of the skin overlying the affected organ is then lightly touched with the cautery. The operation requires only a few seconds, and need not be more than moderately painful. A dressing of iodoform ointment is then applied, and the patient is instructed to wear a suspensory bandage. Instant relief from pain is said almost invariably to follow the employment of this treatment, and the patient, as a rule, is able to be up and walk about in comparative comfort. The author adds that he has also found that

marked relief from pain in gonorrhoeal rheumatism can be obtained by a similar use of the canthary and iodoform ointment.—*Medical Press*, August 1, 1888.

TRAUMATIC SUBDURAL ABSCESS OF THE BRAIN.—In a paper on this subject, in which some cases are recorded, SIR WILLIAM STOKES draws the following conclusions:

1. That after the primary symptoms of cerebral traumatism have subsided, there is frequently a latent period of varying length, during which there are no distinct brain symptoms connected with abscess formation whatever.

2. That their appearance is as a rule sudden, and if uninterfered with, they run a rapidly fatal course.

3. That the occurrence of pus production resulting from cerebral traumatisms is not incompatible with a perfectly apyrexial condition.

4. That this latter fact will probably aid in differentiating traumatic cerebral abscess from meningeal or encephalic inflammation.

5. That both as regards color and consistence there is great variety in the contents of cerebral abscess cavities, and that as shown in Wilm's case, published by Rose, of Berlin, they may become transparent.

6. That antisepticism has largely diminished the risks of the operation of trephining.

7. That having regard to the great mortality of cases of cerebral abscess when uninterfered with, viz., from 90 to 100 per cent., that the operation is indicated even when the patient is in extremis.

8. That in the case where the trephine opening does not correspond to the situation of the abscess, exploratory puncture and aspiration may be employed.

9. That by the adoption of this measure the necessity for multiple trephine openings can be largely obviated.

10. That the employment of a blunt-pointed aspirating needle, as suggested by Rentz, is probably the safest mode of exploration and evacuation.

11. That drainage is desirable in the after treatment of such cases.

12. That both during and subsequent to operative interference in these cases a rigid antisepticism is imperatively required.—*Annals of Surgery*, Oct., 1888.

TREATMENT OF TYPHILITIS.—BOUCHARD'S method is as follows: Soothe the pain by a hypodermatic of morphia, if very sharp; if not use a thick layer of Neapolitan ointment with belladonna, covered by a large and very hot poultice. Give aseptic rectal injections twice a day, with at least a litre of water, to which is added 5 grams of borate of soda, and two or three teaspoonfuls of tincture of benzoin and camphorated alcohol

mixed. Give injections very slowly. Patient must have absolute rest. Give only the mildest purgatives, if any—such as magnesia in water. For diet, milk and alkaline water; later, milk with yolks of eggs. If there is at the end of a fortnight, a thickening around the cæcum, apply a small blister.—*Revue Therapeutique*, No. 4, 1888.

SUBSTITUTE FOR NITRITE OF AMYL.—MM. BALS and BROGLIO describe as the nitrous ether of dimethyl-ethyl-carbinol (amylene hydrate) a very mobile liquid, lighter than water, of an amber color, having an odor similar to that of camphor and terpine, insoluble in water, slightly soluble in glycerine, and very soluble in ether, alcohol and chloroform. While its physiological action is more marked than that of amyl nitrite, it does not cause flushing of the face, and as much as 80 or 100 drops can be inhaled daily.

ANTISEPTIC INJECTION IN SEPTICEMIA.—MOIZARD, in a case of septicæmia occurring in pyo-pneumo-thorax, injected into the pleural sac an ounce of the following mixture:

Tincture of iodine.

Alcohol.

Solution iodide of potass. (1:10) āā ʒij.

The patient recovered, though the case was a very grave one.—*Union Médicale*, Aug. 11, 1888.

HYPODERMATIC INJECTIONS OF ANTIPYRIN.—DERLON advises the use of cherry-laurel water to obviate the pain of subcutaneous injections of antipyrin. He uses the following formula:

R. Antipyrin. grs. 30.
Cocaine hydrochlor. gr. 1.
Cherry-laurel water. ʒj.

This should not be used with morphine injections, since cherry-laurel water increases the pain in these cases.

COMBINED CHLOROFORM AND COCAINE ANÆSTHESIA.—OBOLISOVSKI proposes to inject cocaine at the site of operation after the patient is chloroformed. He claims the following advantages: 1. The local anæsthesia is more effective. 2. Vomiting occurs less frequently. 3. The waking is easier and the after-weakness less. Nervous subjects are sometimes much excited by the cocaine injection.—*Journal de Médecine de Paris*, Aug. 12, 1888.

SOWTHISTLE; SONCHUS OLERACEUS.—DR. S. F. LANDRY has investigated the hydragogue properties of this plant. It acts strongly on the liver, duodenum and colon, and resembles elaterium in causing large watery discharges. It has given good results in ascites and hydrothorax. It should be combined with carbonate of magnesium to prevent griping, or else with manna, aniseed, or some other aromatic stimulant.

BACTERIOLOGICAL EXAMINATIONS AT
AUTOPSIES.

In reading recent medical literature, says BABES, it seems that a precise bacteriological examination is reserved for special cases of infectious diseases. He is convinced that bacteriological researches should be made systematically in all autopsies in infectious diseases. To this end, in the necropsy on man all the precautions should be taken as in the case of an animal; it should be made in a laboratory, where the micro-organisms in the tissues and organs may be collected. In the *Archives Roumaines de Médecine et de Chirurgie*, Babes has a contribution on the technique of such autopsies.

In the first, he says, scrupulous cleanliness of the hands should be observed. The cadaver may be preserved at a temperature of 5° or 6° C. The body should be washed with a 1:1000 solution of corrosive sublimate, and all the water used during the autopsy should be such a solution. The instruments should be sterilized in a stove. The first section of the skin, from the chin to the pubes, should include the subcutaneous cellular tissue and the muscles, and is made with one sterilized knife. Another sterilized knife is then used to open the peritoneal and thoracic cavities. The liquids contained in the peritoneal, pleural and pericardial cavities are then sterilized by plunging a platinum wire into them, and they

are then collected in culture tubes or on plates previously prepared. When these liquids are used for inoculating animals, a sterilized syringe should be used. For the bacteriological examination of organs, the surface of the organ is burned with a hot glass rod over an extent of about 2 cm. The tissue underlying the burn is then torn out. From this fragment is taken, by means of a red-hot platinum wire, a piece to be used for inoculation. The liquids contained in the intestines, bronchi, bladder, ureter, etc., are collected on gelatin plates. At the same time slides are prepared for micro-bacteriological examination by placing on them a few drops taken from the liquids, and leaving them to dry. By means of a sharp sterilized scalpel pieces are removed from the organs and placed in alcohol, for subsequent microscopic examination. At each autopsy at least a dozen slides should be prepared of the liquids and organs, and cultures should be made in moist chambers, and culture tubes with gelatin, agar-agar or serum. During the autopsy several guinea-pigs, rabbits and mice should be inoculated.

We do not know, says Babes, why in man the course of infectious diseases is so variable in different individuals. In the lower animals an experimentally produced infectious disease has, under the same conditions, the same type—an absolute identity, in animals of the same species. "Under the same conditions" seems a sufficient explanation, or at least the key, to the variable course of these diseases in man, since it is very seldom that we find human beings "under the same conditions." Babes says that in making autopsies under the best conditions for the collection of bacteria, he has found that this variability of symptoms in the same infectious disease in different patients is seen especially in cases of complication of the principal disease by secondary infections, also caused by bacteria. In connection with this the reader will remember the editorial article in THE JOURNAL of September 29, on Dr. Bayard Holmes paper on "Secondary Infection in Typhoid Fever." Two years ago Babes presented to the Medical Society of Budapest a bacteriological analysis of autopsies made at the Children's Hospital; and from this it seems that it is the bacteria of diseases consecutive to wounds that more often complicate the infectious diseases and cause death. In the bodies of children dead of infectious diseases, examined a short time after

death, streptococci and some of the five species of saprogenic bacteria are usually found.

An analysis given by Babes shows that it is well to search for and to cultivate the bacteria in all autopsies. Sometimes new bacteria are found, pathogenic for animals. Since in many of the internal diseases the complications that cause death are caused by the same microbes as are found in traumatism, it may be concluded that at some particular time, by reason of the primary disease, the tissues have lost their power of resistance to the invasion of certain bacteria. This is seen in that curious and exceptional complication, malignant œdema in the course of typhoid fever, as described by Brieger and Ehrlich. We must also take into account the frequency of complications due to the habitual association of certain bacteria with certain determined diseases. As an example of this may be mentioned cutaneous gangrene in malignant pustule, due to the presence of micrococci that constantly accompany the bacteria of charbon. In most cases, as already said, it is the bacteria of pus that penetrate the organs, and cause a septicæmia analogous to that caused by suppurating wounds. The chronic infectious diseases, such as phthisis and leprosy, often show local lesions caused by bacteria, as the streptococcus pyogenes, the diplococcus of pneumonia, and sometimes the tetragenus, in tuberculosis; these are habitual causes of the various complications on the part of the lungs or other organs. In leprosy staphylococci are often found. In actinomycosis the abscesses are often found to contain the staphylococcus aureus and streptococcus pyogenes, and it is very probable that the production of pus is due especially to the bacteria that enter secondarily, after the organisms that cause the primary disease.

There are also a number of diseases not caused by bacteria (or not known to be thus caused) that may become the seat of numbers of micro-organisms. This is true of certain tumors, which ulcerate and are invaded by colonies of bacteria. As a rule, tumors are less resistant to the invasion of bacteria than sound tissues. The paper of Babes is a very suggestive one, and his suggestions well worth careful consideration.

DR. JOS. M. WOOD, of Kansas City, died on September 19. He was born in 1810 in Kentucky, and began practice in 1830.

SIR DYCE DUCKWORTH ON MEDICAL BULLETINS.

In a recent lecture to the students of St. Bartholomew's Hospital SIR DYCE DUCKWORTH said: I am strongly of the opinion that at the present time a great deal of apprehension and unnecessary suffering is entailed on our patients, especially in the upper classes of society, by the details and clinical minutiae that too often and most improperly find their place in the bulletins respecting important persons. Such a practice should be firmly discountenanced on every account, and it is certainly satisfactory to know that it does not emanate from the highest ranks of our profession. I believe, further, that many of our patients suffer nowadays more, and are actually less amenable to treatment, than was formerly the case, because there is so much widely spread knowledge of disease conveyed in lay periodicals, and because so many advertisements of vaunted specifics and new remedies are puffed before the public.

Sir Dyce Duckworth said the foregoing in connection with the discussion in clinical lectures, before the patients, of the causation and morbid anatomy, and referred to the practice of the late Dr. Peter Mere Latham, who always withdrew his class from the bedside to discuss these matters. Sir Dyce thinks that such discussions are both inhuman and improper; that we have no right to discuss the horrors of the deadhouse in the presence of patients committed to our charge. While these discussions do not shock us, they may shock and greatly injure the patients, and we must never forget that it is our first duty to be humane, and to regard the patient's interest as first and paramount.

In regard to medical bulletins it may be said that they are the outgrowth of recent years, especially due to the so-called "enterprise" of the newspapers, which first persuaded themselves, and then the physicians, that the public must have all the details possible. In the case of distinguished persons there can be but little objection to the physicians letting the public know how they are in general terms; but it certainly is no business of the public to know all the minutiae of symptoms and treatment, how often a laryngeal mirror is used, a catheter passed, or a nutrient enema given. The newspaper writers and the public do not understand more than a small fraction of the medical terms used in minute bulletins,

and can get but an erroneous impression from them. The fierce quarrel now in progress between Sir Morell Mackenzie and the German physicians in the case of the late Emperor Frederick should be a lasting warning to physicians not to issue minute bulletins, nor air the progress of cases in the newspapers. In the case of a public man ill, the public is interested in the case only to the extent of knowing in a general way *how* he is, not why he is better or worse, what his daily symptoms are, and what the plan of treatment is.

As we all know, the physicians in a case cannot always agree; when they do not agree, and issue bulletins, these are sure to bring the whole matter of disagreement before the public. As a result we find in the newspapers such editorial comments as the following:

"The German bureaucrats are busy burning the book of Dr. Mackenzie. The work shows that it was not he but the native doctors who hastened Frederick to his grave. The physicians of Fatherland will reply with a hundred books at least, and the question of our youth, 'Who Killed Cock-Robin?' will be forgotten in the quest for the great healer who, for a fee of one hundred thousand, gave the sick Emperor that particular *coup* which served him.

"Yet Frederick is as dead as his ancestor, the great Elector. What do the doctors gain by revealing the foibles and the impotency of their profession? So long as no respectable man will die without the presence and attention of a doctor, why should not the learned men rest contented with the respect in which they are held?"

What do we gain but a certain amount of distrust on the part of the public, and too frequently a snub when we go before the public with a matter of importance to the public?

EDITORIAL NOTES.

HYSTERICAL SPASM OF THE ŒSOPHAGUS.—BORGIOTTI records an interesting case of a woman, aged 31, who, having had four attacks of hysterical convulsions, was taken with spasmodic dysphagia at the end of a fever that lasted two months; in addition to the dysphagia was pyrexia, frontal headache, severe pains behind the sternum. At each attempt to swallow, all food was rejected. This œsophageal spasm continued without interruption for 530 days. Oc-

asionally it could be overcome by means of a sound, but it rarely permitted the passage of even fluid food. The part of the œsophagus affected corresponded with the dorsal spine from the fourth to the seventh cervical vertebra; at this point the passage of the sound caused pain. The spasm was finally cured by means of Verneuil's œsophageal dilator. After the first dilatation fluid food could be introduced by means of the sound. On the sixth day the patient could swallow solid food. During the first six days the patient's weight increased five pounds, and the temperature, which had been subnormal for some time, rose to normal.

PREVENTION OF OPHTHALMIA.—DR. LITTLEJOHN, Medical Officer to the Hanwell School, London, at the conclusion of a report on ophthalmia in the central school district of London, summarizes his suggestions as follows: 1. The division of those attacked into small groups. 2. The appointment of a sufficient number of experienced nurses. 3. Abundant open-air recreation for those attacked. 4. A system of cleaning school-rooms, etc., which shall avoid damp boards as the result. Abundant ventilation, especially of dormitories; artificial warmth and extra clothing being utilized when needed. 6. Improvements in bathing and washing; including the provision of large open-air baths. 7. The washing and efficient disinfection of each towel after use. 8. More outing in the country lanes during half-holidays; together with provision of means for exercise and games. 9. Such arrangement of seats in the school-rooms that there shall be no strain on the eyes, and that the sun's rays shall not fall directly on the eyes.

ELECTROLYSIS IN PARENCHYMATOUS GOITRE.—WEINBAUM, of Kovel, describes in a recent number of *Urtch* two cases of parenchymatous goitre cured by electrolysis. The electricity was applied for ten or fifteen minutes at a sitting, supplied by a battery of 20 cells connected with two gold needles; these were thrust several millimetres into the tumor at two points diametrically opposite. Moderately strong currents only were used. In the first case one hundred and fifty séances were had in eight months, during which time the tumor gradually dwindled away. The patient was seen about a year afterwards, and was in complete health. There was no trace of

the swelling except slight cicatrices at the sites of small ulcers made by the needles. In the second case there was but little left of the goitre after fifty séances, and the general health was much improved. Weinbaum tried electrolysis, but unsuccessfully, in a case of dense fibrous goitre.

YELLOW FEVER continues at Jacksonville, Florida, though the number of cases are greatly diminished. The number of new cases reported on the 22d inst. is 43, and deaths, 1. Of the new cases 8 were whites and 35 colored. The whole number of cases reported since the commencement of the epidemic in Jacksonville is 3,839, and the number of deaths to date, Oct. 22, 332. The danger of any general spread of the disease through the Southern States the present season has evidently passed, and most of the quarantine arrangements outside of Florida have been discontinued. The volunteer physicians who have been on duty at Jacksonville are reported to have tendered their resignations because their services are no longer necessary.

APPARATUS FOR RECORDING LATERAL CURVATURES OF THE SPINE.—DR. C. L. SCUDDER describes in the *Boston Medical and Surgical Journal* an apparatus that records:

1. The lateral curvature of the spinous processes of the vertebrae.
2. The outline, height, and breadth of the shoulders.
3. The outline, height, and breadth of the hips.
4. The relation between the arms in the natural position and the outline of the hips.
5. The distance of the scapulæ from the spine.
6. The antero-posterior curves of the back.
7. The curve of rotation in the dorsal region.
8. The curve of rotation in the lumbar region.

The tracings may be easily reduced for records.

AN ITALIAN MEDICAL SOCIETY, on the plan of the German Society of Internal Medicine, is proposed under the name Società Italiana di Medicina Interna. The proposition was to hold the first meeting in Rome this month. Discussions on any one subject are not to exceed one sitting, the introducers of the discussion being allowed half an hour, and subsequent speakers a quarter of an hour. Each introducer is to have ten minutes to close the discussion. Papers must be read within twenty minutes, and for the discussion of them each speaker is allowed ten

minutes, no person being allowed to speak more than once.

OUABAINE, $C_{30}H_{46}O_{12}$, is a crystallizable derivative of Ouabaïo, which belongs to the family Apocynaceæ and grows in the mountains of Comal, Eastern Africa. ARNAUD has isolated from the wood about 30 per cent. (!) of the substance he calls ouabaine, which is slightly soluble in cold water, and very soluble in boiling water, and insoluble in chloroform, anhydrous ether and absolute alcohol. The physiological experiments made thus far show, according to Varigny and Langlois, and E. Gley, that its physiological action is similar to that of strophanthus.

A DECISION IN REGARD TO MORAL INSANITY has been given by the Supreme Court of Connecticut as follows (in *Anderson vs. The State*, 43 Conn., 515): It is true that courts have been slow to recognize this form of insanity as an excuse for crime. Nevertheless, that it exists is well understood, and that in some cases it is clearly defined.

THE VACCINE AND EXPERIMENTAL LABORATORY of the University of Missouri, at Columbia, now announces through Dr. P. Paquine, State Veterinarian, that bovine vaccine will be supplied in the State of Missouri in the first week in November, and the first weeks of February, May and August, 1889.

THE JOURNAL OF OPHTHALMOLOGY, OTOTOLOGY AND LARYNGOLOGY, is the title of a new periodical announced to be commenced in January, 1889, in New York, and edited by Geo. S. Norton, M.D., assisted by Charles Deady, M.D. It is to be issued quarterly, at \$3.00 per annum.

THE SALINE COUNTY (KANSAS) MEDICAL SOCIETY was organized on August 28, with Dr. A. S. M. Anderson, of Salina, President, and Dr. J. R. Crawford, of Assaria, Secretary, and with a charter membership of ten. It meets on the last Tuesday of each month.

DR. GAMALEIA has gone to Paris to explain his system of vaccination against Asiatic cholera. He proposes to go to India in March, to test his methods on cholera patients.

THE SOUTH KANSAS MEDICAL SOCIETY will hold its semi-annual meeting at Hutchinson, Kansas, on November 13.

SOCIETY PROCEEDINGS.

Medical Society of the District of Columbia.

Stated Meeting April 25, 1888.

THE PRESIDENT, T. C. SMITH, M.D., IN THE CHAIR.

DR. J. H. MUNDELL read the history of the case and presented the specimen of

AN HYDATIDIFORM MOLE.

(See p. 592.)

DR. SMITH stated that this was the fifth growth of this character presented to the Society within the past year, thus apparently militating against the statement that it is rare.

DR. PHILIP MARVEL read the history of a

CASE OF PLACENTA PRÆVIA.

(See p. 591.)

DR. MARVEL, in opening his paper, stated that he only wished to confine his remarks to the report of a single case. He had seen other cases, but did not have the requisite data. He interpolated that ergot and pulsatilla failed to produce contraction of the uterus, and that he had never known pulsatilla fail before.

DR. REYBURN had assisted Dr. Marvel in the case. He had regarded the case as hopeless when he saw the woman on the day of the delivery, on account of pulmonary phthisis and a narrow pelvis. She was almost exsanguinated and was without uterine pains—they being absolutely absent notwithstanding the administration of ergot, pulsatilla, stimulants, strychnia, liq. ammoniæ, etc. In reviewing the case he could not see anything that could have been done that was left undone.

THE PRESIDENT asked Dr. A. F. A. King to give the Society the recent orthodox treatment of placenta prævia.

DR. KING: The present orthodox treatment is gradual version by the bipolar method, and getting down one foot and letting it act as a plug, and then bringing down the child as gradually as the cervical relaxation will permit. It is very easy to criticise anyone's treatment of a case. No one man's practice could be taken as a criterion, on account of the small number of cases. But he strongly advised the German bipolar gradual version. He thought it was in just such a case as this that Simpson would have removed the whole placenta first, thus preventing hæmorrhage.

DR. FRIEDRICH had had a similar case on the 10th inst. The woman was in the water-closet and thought she was having a stool, but she was flooding. He tamponed and stopped the hæmorrhage. In the morning he removed the plug and the hæmorrhage began again. Dr. W. W. Johnston was called in consultation and advised him

to continue the treatment and wait for pains. Dr. J. returned at 10 P.M. and, there being some dilatation, they separated the placenta, turned and delivered, but the woman died about an hour later.

DR. KING: What did Dr. Friedrich mean by separating the placenta?

DR. FRIEDRICH: Partial separation.

DR. KING: Rupture of the membranes in the beginning without regard to the viability of the child was recommended.

DR. OBER had seen a lady about five months ago for another physician. Digital examination revealed a complete placenta prævia. The hæmorrhage had been very insignificant and there was absolutely no uterine contraction. He thought best to temporize. When the attending physician returned, about forty-eight hours later, he thought best to deliver at once, notwithstanding the flabby condition of the uterus, to which his attention was called. The doctor turned and delivered at once without an anæsthetic. Four hours after delivery and two hours after Dr. Ober had left the house, the woman died of post-partum hæmorrhage, though she was in excellent condition at the time of delivery. The child lived. In Dr. Friedrich's case the woman did not seem to be much affected by the anæsthetic, though hard to get under its influence.

DR. REYBURN, about three years ago, had seen a case with Dr. Morgan in which both mother and child lived. The head of the child descended and labor progressed well after partial separation of the placenta.

DR. SMITH thought it very unwise to trust to the head as a tampon acting against the margin of the uterus. He succeeded in delivering the child alive in a case in which he had previously used forceps, but the woman died. The next case he lost was one in which he had advised extraction of the child after a slight hæmorrhage upon walking about the floor. About two weeks later she flooded and was delivered by nature, and died of exhaustion about a week later. This case was seen with Dr. Burrows, who told him that he had seen "six cases of placenta prævia, five of which died and the other was not a case of placenta prævia."

DR. M. MUNCASTER favored the use of cannabis indica in 10 to 15 drop doses.

DR. MARVEL had seen four cases of placenta prævia: one in his own practice, two in consultation, and the one reported to-night. In his own case he thought it was hydrorrhœa at the first flow, and it was not until the second hæmorrhage, at the eighth month, when he made out partial placental detachment. In one case both mother and child lived. In three the mothers died. In two he used Barnes' dilators; in one turned. Would like to have heard something about the causes of placenta prævia. According to Goodwin, Mundé, Lusk and others, rapid labor should

be induced after the sixth or seventh month. Penrose taught to temporize at first, but if danger threatened to dilate and deliver. Goodell sanctions this.

Stated Meeting, May 16, 1888.

THE PRESIDENT IN THE CHAIR.

DR. ROBERT T. EDES read a report of
A CASE OF CEREBRAL TUMOR.

History.—A lady, aged 58, some three years ago had neuralgia in the head, which was cured, as she supposed, by massage. For two years she had epileptiform convulsions, together with slighter attacks resembling petit mal. Both were followed by temporary aphasia, and the more severe ones by slight signs of right hemiparesis. Headaches were neither frequent, severe nor localized. There was no hemianopsia, and the fundus of the eye, which, however, was not examined for nearly a year before death, was normal. A few weeks before death the aphasia and paretic symptoms became more marked and persistent.

There was a sarcoma on the left occipito-temporal lobe between the fourth convolution (lobulus fusiformis) and the posterior horn of the ventricle. The point of the temporal bone was softened. The island of Reil was swollen and pale, and under the microscope showed proliferation of the superficial layer and degeneration of the deeper pyramidal cells.

DR. SCHAEFFER had examined a tumor of this kind removed from a patient of Dr. J. T. Young. It was a sarcoma, situated in the left anterior lobe, and surrounded by a distinct capsule. The history was very meagre; headache was very prominent and was the only symptom dwelt upon by the physician. Mental derangement was absent. The tumor was adherent to the inner surface of the temporal bone, ovoid in shape, and one and a half to two inches long.

DR. KLEINSCHMIDT: The paper gives a correct history of a very interesting case. The diagnosis was in doubt and could only be made with difficulty. The recent advances in brain surgery make this case more important. Could it have been possible to have made out the location of the tumor in this case from the history? By no means. A lesion may involve either the frontal, occipital or sphenoidal lobe without showing any motor, sensory or special symptoms. This tumor was located in a locality of which we know the least. There was no disturbance of vision. Dr. Edes said there was amnesic aphasia and correctly believes that the lesion in the island of Reil was not the most important.

DR. EDES: The symptoms were due to the secondary lesion and not to the primary. It was not possible to have diagnosticated the location of the tumor from the symptoms.

(To be concluded.)

Gynecological Society of Chicago.

Regular Meeting, Friday, June 29, 1888.

THE PRESIDENT, HENRY T. BYFORD, M.D.,
IN THE CHAIR.

DR. DANIEL T. NELSON presented a

SARCOMA OF THE OVARY WITH HALF-TWISTED
PEDICLE, REMOVED BY AUTOPSY.

I first saw the patient in consultation several days before she was taken to the hospital. She was a patient of Dr. J. E. DeWolf, of Englewood, whom I invited to be present to-night, but unfortunately, he had a professional engagement. She was taken to the Woman's Hospital, but operation was delayed from one day to another, waiting for her to improve in condition, which she never did, and we have the tumor here by post-mortem removal. Her history is very scant, and yet some points in it are of interest, and will raise queries that I trust some of you will be able to answer.

Mrs. M. entered the Woman's Hospital June 7, 1888; occupation, housewife; age at puberty, 12; age on entering the hospital, 39. She was born in America of French and German parents; twice married; the first time seven months, second time seventeen years. She was the mother of nine children, one by her first husband and eight by her second. After the birth of her last child, seven years ago, she did not menstruate for four years; since that time there have been irregular menstrual periods. It is so stated in the history, and yet I think we should rather say there were hæmorrhages from the uterus during these past four years. One year ago she noticed a fluid discharge from the rectum. This is a nice question in pathology, to my mind. She gave evidence of some inflammatory process in the right ovarian region—tenderness, soreness, some elevation of temperature, was confined to bed for a time, and there was a sudden discharge of a considerable quantity of blood. Such quantities are never rightly estimated, but the amount was guessed at by the patient at more than a pint, and supposed by her to have passed from the rectum. Perhaps that was not correct; at all events, after that bloody discharge, she was relieved of the swelling, the tenderness, the inflammatory process, whatever it was, and resumed her ordinary duties. Some time afterward, but unfortunately the record does not say how soon afterward, she began to suffer from swelling in the same region, that continued up to her death. There was constant soreness in the right inguinal region; three months ago the abdomen began to enlarge and she to gain in flesh, strength, and vigor, so that her attending physician, without making a local examination, and especially her neighbors, supposed she was pregnant. She felt

comparatively well until four weeks previous to entering the hospital, when she began to suffer severe pain, tenderness in the right inguinal region, and there was evidence of some kind of tumor. On going to bed with her last illness, about a week before she entered the hospital, her physician became satisfied that there was something more than pregnancy, that there was inflammation of some type. Some days before she entered the hospital I saw her in consultation, and advised a removal to the hospital in the hope that there might be some kind of an operation for her relief. On entering, her temperature was $100\frac{2}{3}^{\circ}$ F., pulse 104. The following day the temperature was $100\frac{1}{3}^{\circ}$ F., pulse 132; the following afternoon the pulse was 132, temperature 100° F. and a fraction. On the morning of the fourth day the temperature ran down to $99\frac{1}{2}^{\circ}$ F., and the pulse to 119. Possibly an operation might have been performed then, and her life saved, but a more convenient and better time was sought for, that never came. There were the usual evidences of peritonitis, and death in the usual way followed. When she first entered the hospital her bowels were moved, but not afterward; vomiting came on the third day, but passed off on the fourth, when probably an operation could have been performed with the possibility of saving life. She died on the sixth day after entering the hospital, and a few hours after death a post-mortem examination was made and this tumor removed. The appearance is somewhat changed now, but yet it presents fairly well the appearance at the time of the autopsy. You notice the dark, venous, congested appearance of a portion of the tumor. This was the anterior portion as it presented against the abdominal wall, very slightly adherent; no adhesions from old inflammation, either to omentum or other structures, but a *half-twisted pedicle*. The pedicle has been tied in such a way as to retain that appearance as much as possible. Here we have the broad ligament that is simply half-twisted and tied in that position on purpose. The evidence of completely twisted pedicle and death of the tumor were not present. There was simply an increase in size resulting from the congestion, but no sloughing, no death of the part—a slow, inflammatory process had taken place in the tumor and subsequently in the peritoneum, that was the cause of death. The obstruction of the bowels, I believe, was due to the peritonitis, and not to pressure from the tumor. It has not been my privilege to see a patient with a tumor and twisted pedicle, but it seems to me I could have recognized it; but this being only half-twisted, the circulation was impeded, not stopped. The tumor has been examined by Dr. Frank Carey, and the report is sarcoma. There was, so far as I saw, and I made a rather hurried examination, no evidence of the disease extending to other

organs; there is no evidence of it in the pedicle; there was no evidence in the glands or intestines or structures adjacent, so it seems as if it could have been entirely removed if the operation had been performed during the life of the patient. The uterus was a little enlarged, but no other evidence of disease about it. I made a diagnosis of malignant tumor, without being exactly certain as to its nature, but it seemed to me malignant on account of its rapid development and the age of the patient. I did not regard it as a uterine tumor, as the uterus was movable and the tumor seemed to be separate from it. Within the abdominal walls there was a considerable amount of ascitic fluid, so that the abdomen was very tense, and it was difficult to say whether or no the tumor could be moved readily within the abdominal walls. I was unable to say whether or no there were adhesions, but from the ascites I hoped not.

DR. ETHERIDGE: The doctor said that if the pedicle had been completely twisted he could have determined it. I would like to ask how?

DR. NELSON: The evidences of acute inflammation would have been much more rapid and severe, also the appearance of shock. In other words, the patient would be something in the condition of one with an internal hæmorrhage, there would be evidence of greater disturbance that would come on suddenly after exercise, while in this case there was no sudden beginning of the evidence of inflammation, it came on gradually.

DR. ETHERIDGE: Did you diagnose a solid tumor?

DR. NELSON: It seemed to me that it was; there was considerable fluctuation and ascitic fluid, but it seemed to me a solid tumor, and that was my reason, together with the age of the patient, for believing it was malignant. I supposed it was carcinoma and not sarcoma. I would like to ask whether that hæmorrhage, indefinitely described as from the rectum, could by any possibility have been the result of a congested condition of the tumor that was freed by an opening through the Fallopian tube, the pedicle having been untwisted, and whether the attack a year or more ago was similar to the one she died of, only the pedicle was more twisted this time, so nature could not relieve herself in this way. In reply to Dr. Etheridge, he said that the rectum was not examined.

DR. FINGER: As a rule, under other circumstances, malignant tumors have as one of their main characteristics invasion of the surrounding tissues and, consequently, adhesion and inflammation enough to bind the tumor to the surrounding organs. But we know that, in sarcomas or carcinomas of the ovary, it is common to find, as in this case, no adhesions. This fact is probably explained by the early setting in of ascites, as we know that the presence of fluid, ascitic fluid, saline solution, etc., in the abdominal cavity, helps

to prevent adhesive inflammation by keeping the tumor away from the loops of intestine.

DR. HENRY T. BYFORD: I examined the patient once, in life, and was present at the *post-mortem* examination. I satisfied myself that the tumor was not connected with the uterus, for although pressing upon the tumor moved the uterus, yet lifting the tumor did not. The course of the disease appears to have been, first, the twisting of the pedicle, then venous congestion, bursting of small blood-vessels, rapid distension and inflammation of the tumor, especially on the side that we now see to be black. The case was not one of ordinary peritonitis; there was not much tenderness, except when the tumor was directly pressed upon. Intermittent attacks of partial obstruction of the bowels, due, undoubtedly, to the presence of this heavy tumor, hastened her death.

DR. CHRISTIAN FENGER presented a

FIBRO-CYSTO-SARCOMA OF THE UTERUS.

This specimen was removed by laparotomy from a woman of 35, who had a tumor the size of a child's head, immovably connected with the uterus at the fundus, and also two small myomas that could be felt through the vagina. The large tumor showed fluctuating places on the surface, by palpation through the abdominal wall, and I concluded that it was an ovarian cystoma, either located in the broad ligament or sufficiently adherent to the uterus to make them move together. At the operation I found it to be a cysto fibroma, or fibro-cysto-sarcoma, subperitoneal, but attached by the broad base to the uterus at the fundus. After temporary elastic constriction around the cervix, the tumors were enucleated, and as the uterine cavity was not opened, I united the wound of the wall of the uterus with buried step sutures, deep and superficial, and a final continuous suture along the inverted borders of the peritoneum.

At the close of the operation all hæmorrhage had apparently stopped, consequently I did not drain. In the course of the first week some fever set in, and on the tenth day I reopened the lower border of the wound and evacuated about three to four ounces of blood mixed with pus, from a cavity surrounding the body of the uterus. The evacuation and subsequent washing out and drainage did not have much influence on the patient's condition; the fever continued, she had a large gangrenous bed-sore over the os sacrum and died six days later, in the third week after the operation. The autopsy showed no peritonitis, and the cavity with the accumulation of blood and pus was found entirely separate from the general peritoneal cavity. On examining the uterus I found, as you see here, surrounding the line of the uterine wound, an island of gangrenous tissue including the wound and a square inch or more to each side.

This gangrene explains the persistence of fever and sepsis, notwithstanding the evacuation and drainage.

The large inner tumor has, you see, a smooth surface. On the cut surface, in some parts, there was an appearance of myoma, in other places, islands of softer tissue looking like myxoma or sarcoma, and in other parts cystic cavities. These cysts have not the usual shape and appearance of cystomata, but are irregular, triangular, or longitudinal sinuses, the walls of which are not smooth but trabeculated, so as to give the appearance, as Dupuytren describes it, "similar to the walls of the ventricles of the heart."

I shall here make a few remarks on fibrocystomata of the uterus, because they are comparatively rare, the whole number described in the literature not being much above 100. Fibrocystomata are, as the name indicates, forms of fibromata or myomata, and it is a comparatively rare change in the preëxisting elements of these tumors that gives them the additional characteristics of cystomata.

We distinguish between the following varieties: myxomyoma, as described by Virchow, characterized by œdema of the interstitial tissue, and by the fluid in the spaces containing mucin; consequently it is something more than a simple œdema of the myoma. Spread islands of embryonal cells are also proof of a more active process, terminating in myxomatous or even sarcomatous tissue. Besides the œdema in the interstitial tissue of the myoma, we find œdema and atrophy of the muscular fibres, isolated fibres or their débris mixed with the fluid in the cavities. These cavities are of all sizes, from the microscopic, as shown on this slide, up to the size of a pin's head or walnut, and we even find cavities of enormous size, containing several quarts of fluid. The cavities are lined with pavement-celled epithelium, or rather endothelium, as you would expect, since they originate from dilated lymph spaces, or naked when the cavity is formed by the disintegration of muscular fibres. The cavities contain clear, colorless, or bloody fluid that often coagulates spontaneously when evacuated—a fact that Atlee pointed out as a differential diagnostic sign in contradistinction to the fluid from ovarian cystomata. A special form is described as fibromyoma lymphangiectodes, by Leopold. Distinctly different from this is the myoma teleangiectodes sive cavernosum of Virchow, with multiple cavities from the size of a millet-seed to that of a pea, communicating with the blood-vessels and consequently containing pure blood. These tumors are found to enlarge during menstruation (Virchow), and on auscultation a bruit is heard (Péan).

As to the place of development, the great majority are subperitoneal. Of the 70 cases gathered from the literature by Heer, 63 were subserous, 5 interstitial and only 2 submucous tumors. They

sometimes attain an enormous size, weighing 29, 40, and in one case even 81 lbs.

The cystofibromata are most often found between the ages of 30 and 50. The symptoms are in the main, of course, the same as those of common myomata and fibromata. Uterine hæmorrhage is rare because, as before mentioned, they rarely develop close to the mucous membrane. A more characteristic symptom is a sudden enlargement, probably from acute increase in the size of the cysts or from intracystic hæmorrhage. The spontaneous coagulation of the fluid would be a valuable symptom if it was constantly found, but in about seventy cases it was noted in only eleven (Heer). It might, however, in reality be more frequent, since in a number of cases it might not have been noticed (Gusserow). The lack of vitality shown by the tendency to local gangrene is also somewhat characteristic of these tumors. Thus Grammaticati, as stated by Gusserow, saw a myoma the size of a child's head, located in the wall of the cervix, undergo superficial necrosis, followed by sepsis and death.

It is rather noteworthy that a correct diagnosis was rarely made. They were almost always taken for ovarian cystomata, and a number of them were punctured. Puncture, however, in this form of cystoma, is far more dangerous than in other cystomata, as shown by Leopold, who found that, as a consequence of puncture, ten patients out of eleven died. McGuire, therefore, is right in asserting that exploratory laparotomy is less dangerous than puncture.

The treatment should be early extirpation, because of the probability of rapid enlargement, the danger of puncture, the liability to gangrenous or septic changes, and thrombosis of the vessels in and around the tumor. Gusserow gives a series of 41 laparotomies with 22 recoveries, the cause of the high mortality being the necessity of the removal of the uterus in some of the cases. Occasionally the operation cannot be finished; thus, according to Gusserow, in 38 cases, 7 were unfinished, and of the 7, 6 patients died. That an exact diagnosis, with a definite premeditated plan of operation, is of extreme importance, is shown by Gusserow, who, out of 11 cases described in the literature, reported 9 recoveries.

A few words about uterine sarcomata, inasmuch as the tumor here presented is a mixed form of cystofibroma and sarcoma. In the uterus we distinguish between circumscribed and diffused sarcomata, the former originating in the muscular wall of the uterus, the latter in the mucous membrane. The circumscribed uterine sarcomata are of the most interest to us in this connection, as they stand in near relationship to fibromyomata and fibrocystomata. They form, usually, round, circumscribed, harder or softer tumors, looking like, and developing in the same places as the fibromyomata, and so similar to these that we

must class the relapsing fibromata of Paget among the sarcomata. But besides more or less typical fibrous or muscular cells, here we find islands of short, spindle-shaped, round or polymorphous cells, or islands of myxoma tissue; in general, a more vivid cell-formation than in fibromata and myomata; and we further find in the same tumor in different places different forms of cells. So predominating, however, are fibroma or myoma tissue cells that Schröder regards it as a law that the circumscribed sarcomata are always formed by transformation of fibromata. According to Gusserow, the transformation of fibromata into the mixed form of fibrosarcomata, myxosarcomata, and cystosarcomata is so rare that the literature shows very few well-observed cases of this kind. By examining the microscopic slides that I exhibit to-night we find, in some portions, apparently typical myofibroma tissue, without or with dilated lymph spaces, in which we find granulated matter containing loose or isolated muscular cells; in other places, islands of typical myxoma tissue, here and there islands of embryonal cells; in another part of the tumor, territories of short, spindle-shaped cells, large and with oval or round nuclei; in other words, islands of unmistakable sarcoma tissue; and finally, places of common typical, round-celled sarcoma tissue.

As to the age in which fibrosarcomata of the uterus are found, there is this difference from the cystofibromata, that, while they both are most common between the ages of 30 and 50, the sarcomata are still common between 50 and 60, while the cystofibromata, as we have seen, stop at the age of 50.

As regards treatment, the sarcoma is a malignant tumor and needs more extensive removal or radical treatment than the benignant cystofibroma. The removal of subserous or interstitial fibrosarcomata by abdominal supra-vaginal extirpation and extraperitoneal treatment has often been followed by a growth of sarcomatous tissue in the cicatrix in the abdominal wall. The abdominal total extirpation of the uterus can hardly be said to have lost much of its dreadful mortality of about 70 per cent., from the time of Freund's first operation till now.

In the treatment of this case, the following suggestion occurred to me—a suggestion which was not carried out because of the patient's death. I should operate as I did, enucleating the subserous tumor, and if the uterine cavity was not opened, try intraperitoneal treatment of the stump. After recovery from this operation, if the microscopic examination of the tumor proved it to be a fibrosarcoma, I should follow, as soon as the patient's strength would permit, by vaginal extirpation. In the rare cases in which the size of a diagnosed circumscribed uterine sarcoma or fibrocystoma will permit of vaginal extirpation, this operation is, of course, the only one indicated.

The two other specimens are not strictly gynecological, as they occurred in men. However, they had this in common with gynecology, that laparotomy had to be done.

COLLOID CARCINOMA OF THE CÆCUM.

This specimen is a tumor of the cæcum, a so-called colloid carcinoma. The patient was a man of about forty, in whom, for about six months, an increasing tumor had developed in the middle of the abdominal cavity. When I saw him the tumor was of the size of the head of a child of four, was somewhat movable from side to side and up and down. There were never any disturbances from the side of the intestines, but emaciation and considerable pain. I thought it a tumor of the omentum on account of its mobility, also that it was malignant because it was hard, nodular, and of rapid growth, but I did not think of the intestine being the seat because there were no symptoms. When the abdominal cavity was opened I found this large nodulated tumor with a great many adhesions to the omentum and some to the intestines, and finally having separated these and applied a great many ligatures, when I got the tumor isolated and out through the abdominal wound, I found the ileum passing into one side of the tumor and the ascending colon coming out of the other side. I then divided the ileum and ascending colon two inches away from the tumor, detached and ligated the mesentery, and after the removal of the tumor closed the ileum and ascending colon in the usual way by invagination and suture, and made an anastomosis between the lower end of the ileum and upper end of the ascending colon by means of Semm's decalcified bone plates. The territory of approximation was covered by an undetached omental flap. I preferred this operation to circular resection or implantation of the ileum into the colon, because of the shortness of the plate operation as compared with the others. The patient lived four days, was able to take some liquid nourishment, had no vomiting, no tympanites, showed no symptoms of sepsis or peritonitis, but gradually became weaker and died. The autopsy showed no peritonitis, the ends of the upper and lower bowel were closed, as you see in this specimen, the closed ileum and closed end of the ascending colon, and at a distance of two and a half inches the anastomosis covered with the omental flap, which did not adhere. The peritoneal surfaces between the plates are perfectly united, allowing of no escape of liquid or air. The passage between the ileum and colon is perfectly free, as you see after opening the opposite wall of the intestines. The tumor shows at this point the ileum entering the large irregular cavity containing some liquid feces, slightly tinged with blood, and at the upper end of the cavity is the ascending colon. This enormously thickened wall of the cavity, one and a

half to two inches in thickness, is the carcinomatous intestinal wall, the cut surface presenting the characteristic gelatinous appearance of colloid carcinoma. This form of carcinoma has as its characteristics, in distinction from other carcinomas, colloid degeneration of the cells, causing them to enlarge, meet together, and form this transparent gelatinous substance. While we do not recognize a colloid carcinoma as distinctly different from carcinomas in general, as we know that partial colloid degeneration is common in all carcinomas of the intestinal tract; clinically, we recognize the extremes of this degeneration as a distinct form, characterized by its enormous size, and not uncommon in the stomach, large intestine, and peritoneum. In the peritoneal cavity there were no secondary tumors nor were the lymph glands of the mesentery invaded. This is what we should expect, as this colloid carcinoma is, as a rule, relatively benignant, with little tendency to the invasion of distant tissues or organs.

The death of the patient I ascribe to the fact that when the vitality has been lowered to a certain point by malignant tumors, without or with functional disturbances of vital organs, the organism loses its power to sustain more than a certain amount of operating, and death will follow from the yet unexplained exhaustion, in spite of the absence of all the common well-known fatal complications.

DOUBLE CARCINOMA OF THE COLON.

The third and last specimen is from a man between 40 and 50, who had suffered terribly from difficult passages from the bowels for a number of months. Finally a small, almost immovable tumor, appeared to the right of the umbilicus, and later on distention of the small intestines with pain and vomiting. Every half-hour or hour there would be a paroxysm of peristaltic contractions with excruciating pain. He finally asked to be relieved at any risk. On account of his extreme emaciation and weakened condition, I thought it out of the question to attempt extirpation, and resolved to try to relieve him by means of anastomoses between the intestine above and below the stricture. Laparotomy revealed the tumor to be a carcinoma of the ascending colon; consequently I united the lower part of the distended ileum with the empty transverse colon five to six inches away from the tumor. The patient did not get much relief and died ten days after the operation, growing gradually weaker, as in the other case. The autopsy showed no peritonitis, the omental flap was partially adherent to the intestine, the peritoneum between the plates united, but at the distal end of the plate, in the colon, an island of necrosis of the intestinal wall from pressure-atrophy caused by the plate. Thus in this case perforation of the intestine was only a question of a short time.

The carcinoma of the ascending colon, as the specimen shows, is three inches long and has caused almost complete occlusion of the bowel. The reason why no relief followed the operation was found below the anastomosis in the splenic flexure of the colon where a second carcinoma had developed, causing as you see, almost complete obstruction of the colon. This second carcinoma was not discovered during the operation, as it was hidden high up, under the spleen. The emptiness of the transverse colon, together with the rarity of a second carcinoma, was the cause of my not suspecting its presence. If it had been discovered, the anastomosis would have been made between the ileum and the sigmoid flexure of course. The mortality from even palliative operations upon the intestines is large, because, as a rule, the patients do not come to us for operation until they are exhausted by serious intestinal disturbances, usually of long continuance. This is so generally the case, that collapse, even after a short operation, is of frequent occurrence.

Senn's operation of intestinal anastomosis with the plates does not take any more time than the abdominal operation for artificial anus. The last operation here mentioned was of thirty-eight minutes' duration, from the time of the incision in the abdomen to the dressing of the abdominal wound.

DR. ETHERIDGE: I would like to ask Dr. Fenger if he thinks that, if he had drained the first case, he would have saved her from any gangrenous affection?

DR. FENGER: That is possible.

DR. ETHERIDGE: Why did you not do vaginal hysterectomy?

DR. FENGER: Because the tumor was too large.

DR. ETHERIDGE: If you had a similar case, would you not, after liberating the tumor through the abdomen, make a vaginal hysterectomy?

DR. FENGER: No; not at the same time, because I think that is dangerous—too much operating.

DR. ETHERIDGE: It seems to me that the combination of the two in an operation that, if not prolonged too much, increases the chances of the patient to live. You would have magnificent drainage that way.

DR. FENGER: Is not that a combination of abdominal and vaginal hysterectomy?

DR. ETHERIDGE: Well, cases get well after hysterectomy, even where the abdomen is opened?

DR. FENGER: That is Freund's operation.

DR. ETHERIDGE: Freund's and Schroeder's.

DR. FENGER: What is the difference; is it not the combination of laparotomy and vaginal hysterectomy that brings the mortality up above 60 per cent?

DR. ETHERIDGE: Have the two been done enough to make such a mortality as that; have

enough cases been recorded to say that there is a mortality of 60 per cent.

DR. FENGER: What is the difference between that and Freund's operation?

DR. ETHERIDGE: You have better drainage in Freund's operation.

DR. FENGER: From what I think now I would be afraid of that combination.

DR. ETHERIDGE: I have often thought if I should have a case of tumor of the uterus to remove and the adhesions were not enough in the pelvis to fix the cervix immovably, I should make the operation through the abdomen of removing the tumor, put an elastic ligature down as far as possible, then immediately remove the cervix by vaginal hysterectomy depending upon the forceps for control of the hæmorrhage. In that way we could get a magnificent drainage through the vagina.

DR. FENGER: Time would first have to show if such a combination as that would bring Freund's mortality down.

DR. ETHERIDGE: I believe a great many cases of fatal termination of supra-vaginal amputation of the uterus is from lack of drainage, and if after the amputation the balance can be taken out through the vagina, then we can close the abdomen and have the drainage through the vagina. Of course, that could not be done if there were universal adhesions through the pelvis.

DR. FENGER: Frank, of Cologne, who, criticised so much about his ten cases of enucleation, believed that he could peel off the uterus and leave the peritoneum. If that can be done in all cases, which I consider impossible, it can be done much more easily when there are adhesions all around the uterus. In fact, one of Czerny's first operations for uterine sarcoma was done in that way—vaginal enucleation without opening into the peritoneal cavity.

DR. EARLE: Suppose these operations had been successful, how long would they have prolonged the men's lives?

DR. FENGER: The man with double carcinoma would die in due course. In the other case—the colloid carcinoma—it is well known that these carcinomas belong to a comparatively benignant type, and there is nothing against the possibility of a radical cure.

DR. NELSON: I wish to remind Dr. Fenger that he has not explained the cause of gangrene.

DR. FENGER: I will take into consideration first the way in which the wound surface is treated, namely, by a double row of sutures, deep and superficial. That is not enough to cause gangrene. Then comes the liability of these tumors in general to local death, and then comes sepsis. Sepsis plays an important part in the etiology of gangrene, and I do not doubt that sepsis in the collection of blood around the uterus was a main factor in this case.

DR. NELSON: Might there not be an explanation through the nervous system by the destruction of some important nerves?

DR. FENGER: The nervous system is far away. We know so little about gangrene by the destruction of the nerves that we are not able yet to take that up as a factor of much prominence. We hardly know of any gangrene from nervous destruction alone. The decubitus in paralytic patients is a mixture of traumatism and lack of innervation. The same may be said of the destruction of the joints in locomotor ataxy. There is always an element of injury, consequently something more than mere lack of innervation. In this case, I do not believe that the question of nerves would play any part.

DR. NELSON: Could there be a sufficient spasm of the muscular structure left behind to destroy the nutrition of the part?

DR. FENGER: Contractions can, as we know, sometimes make a fibroid die.

THE PRESIDENT: I intended to exhibit, for Dr. Wm. H. Byford, a uterine cysto-myoma possessing all the characteristics of the one just presented by Dr. Fenger, but found to-day that the specimen had been allowed to spoil. It was pediculated, slightly adherent in places, trabeculated within, and quite full of collections of serum that coagulated upon exposure to the air. The patient was operated upon two weeks ago and is passing through a rapid and easy convalescence. The pedicle was treated extraperitoneally, and the abdominal cavity closed without drainage.

FOREIGN CORRESPONDENCE.

PROF. VON PETTENKOFER.

His views on Cholera and Typhoid Fever—On the Efficacy of Quarantine—On Yellow Fever.

There is no man in Europe to-day that stands as high in Sanitary Science as Prof. v. Pettenkofer. To him Munich owes its diminished mortality from typhoid fever. To him the world owes a vast amount of information concerning epidemics. And to him nations will owe a large immunity from zymotic disease should his views be accepted and put into practice. He is a determined non-believer in the personal contagion doctrine of cholera, typhoid and yellow fever. Hence he sees no practical utility in quarantine. Indeed he believes it to be detrimental in propagating false ideas and exciting needless alarm. His facts tend to explode any credence in the rôle played by drinking water. He sees in the soil and sewage the cause, and the cause only of epidemics. His opinions are backed by over forty years of intelligent study, and by collateral experiments and observations of others in the same line of inquiry.

I had occasion to visit the Hygienic Institute this morning in order to obtain from the Professor his views upon the following points:

1. The rôle played by microbes in the production of zymotic disease.
2. The efficiency of quarantine.
3. The best measures to prevent the spread of an epidemic.
4. Views on yellow fever.
5. Vaccination as a preventive.

To his answers, full, concise and convincing, I intend giving the widest circulation possible during the course of the next ten days, because it seems to me that the laity should be amply informed in all matters touching upon the public health. It is not then for this purpose that I now write, but to give briefly some more interesting sparks from a mind that is running over with brilliancy and full of scientific lore. In connection with the etiology of cholera, Prof. v. Pettenkofer took me to his chart-room, to illustrate the fluctuation in the course of typhoid fever in Dantzic and Munich, beginning in the year 1852, and affected by the improvements in the drinking water supply and in improved methods of sewerage. The charts covered rainfall, the amount of ground water, the actual death-rate and the relative death-rate. In the appropriate years were noted the introduction of the new reservoirs, as well as of the improvements in drainage. When the ground-water fell the mortality was larger. When it rose the death-rate was smaller. In 1852, in a population of 100,000, 350 died of typhoid fever. Then the people attacked the water. It was examined by experts and found to be perfectly pure. Würzburg, with a water-supply much less pure, had no typhoid fever. Yielding to public pressure, the city inaugurated a new water supply. The following year the death-rate fell. But the next year and in those following it reached its former formidable proportions. Then Pettenkofer agitated his drainage reforms—the cleaning of the earth, so to speak, and the proper disposal of refuse. Since this time the mortality has steadily diminished, until now the deaths from typhoid fever are extremely rare.

Certain soils tend to cleanse themselves rapidly, others require more time, and to utilize this point is one of the achievements of modern Sanitary Science. In Dantzic the conditions were the same as in Munich. A change of drinking water supply gave no better mortality, but when the whole system of drainage was changed for the better the death-rate at once diminished. These epidemics usually follow stagnant water courses, and wherever still, foul water exists zymotic disease will also obtain. Cholera only obtains in districts badly drained—meaning by this every condition of soil for which drainage was inaugurated. In New York, in 1852 (I think it was, the exact date has escaped me), the cholera

attacked only a part of Blackwell's Island and only a part of New York, and that was around the docks and lower part of the city. People visited the infected places, contracted the disease, and died with it in other precincts of the city, and yet no one else in these districts contracted cholera. In Munich during a distressing epidemic certain sections remained entirely healthy.

Dr. Cunningham, of Calcutta, is now passing through the press a large book, in which by a large amount of investigation extending over many years in India, as well as by experiments in the laboratory, he shows Pettenkofer's views to be the only correct ones, and gives the Professor, now covered with years and honors, credit for being the first scientist to place upon a proper footing the question of epidemics. Both of these gentlemen have no belief in quarantines. Their history at any time in the world's history, and whenever enforced, have never shown them to be productive of preventing the spread of an epidemic or of arresting its localized progress. America with a strict quarantine is scourged, while England with no quarantine escapes. The advance of any epidemic can only be arrested by improving the conditions upon which it depends for an existence, and history fails to record a single instance in which it has been stopped in any other way. At a time when Montevideo was suffering disastrously from yellow fever invasion a doctor in charge of the hospital there succeeded in quieting the people who had a superstitious dread of contagion that it *was not* personally contagious by taking his two young children with him each time that he made his visits to the fever wards.

I send this merely as an *avant courier*. A more elaborate expression of Dr. v. Pettenkofer's views will be published later.

HORATIO R. BIGELOW, M.D.

Munich, Oct. 4, 1888.

DOMESTIC CORRESPONDENCE.

LETTER FROM NEW YORK.

(FROM OUR OWN CORRESPONDENT.)

Hypnotism; its Therapeutic Uses—Therapeutic Value of Hypnotism.

There was an unusually interesting session recently of the Neurological Section of the Academy of Medicine, when the somewhat uncanny subject of hypnotism was dispassionately discussed in a purely scientific and rational manner. The principal paper of the evening was by Dr. C. A. Herter, on *The Therapeutic Uses of Hypnotism*. He said the employment of this agency was attended with considerable difficulty on account of the prejudice existing against it in the minds of the profession, as well as the public; and it was per-

haps impossible at the present time to arrive at any positive conclusions as to its proper place in medicine. Hypnosis resembled ordinary sleep, with the element of "suggestion" added. Suggestion was effective, however, in the waking state also, as shown in the so-called Christian Science and faith cure, as well as to some extent as regards homeopathy.

Dr. Herter adopted the classification of Lieboldt, who makes six divisions of hypnotic trance, according to the degree of its intensity, in contradistinction to that of Charcot into catalepsy, lethargy and somnambulism, and said that he did not think that Charcot's cases should be taken as a basis for conclusions because they were, as a rule, in trained subjects. He then described the proper method of inducing hypnosis, as advocated by Lieboldt and Bernheim. The operator should first secure the confidence of his patient, and then tell him to look him steadily in the eye and think of nothing but going to sleep. The process could be materially aided by suggestive remarks addressed to the patient and by placing two fingers upon the face; the fingers being finally pressed gently upon the eye-lids. In order to obtain good results it was necessary to watch the patient very closely, and to suit the words to the symptoms of sleep as they developed themselves. The *rationale* was very simple. Verbal suggestion in the waking state made the subject believe that he was falling asleep, and the method closely resembled the natural process.

Of the various conditions in which hypnotism has been employed therapeutically Dr. Herter first spoke of hysteria. More attention, he said had been given to its use in this connection than any other, but notwithstanding all that had been written upon it, the special indications for resorting to it are still far from clear. It was probable that hypnotic suggestion might be of more or less service in all forms of hysteria; but, as a rule, recovery, if secured, was not permanent. Its effect on hysterical amaurosis and amblyopia was extremely interesting, and in many cases a very marked improvement in vision had attended its persevering use. Of the motor paralysis none are more benefited by it than abductor paralysis of the larynx. In hysterical convulsions the number and novelty of the attacks were greatly diminished. No one, he thought, need ever be discouraged by failure to secure hypnosis at the first trial in any case of hysteria. The prospect of a cure would depend on various circumstances, but at all events hypnotism would in many instances serve as a useful adjunct to other treatment.

Not much was to be hoped from it in hystero-epilepsy, and the same was true as regards ordinary epilepsy. In some cases of chorea he stated that the effect on the movements was rapid and marked, and with perseverance a cure might be

effected. A number of daily sittings was generally required, and in some cases it was necessary to keep them up for months. In any case of supposed cure, however, there would always arise the question whether the disease had not simply run its course and ended spontaneously. There was the most ground for hope in those cases in which the movements were general, and the previous existence of rheumatism and endocarditis did not seem to render the chances of relief less favorable. In insanity the results from hypnotism had not for the most part been satisfactory. He had seen it tried quite extensively at Zurich, but had never observed any benefit from it that was not evanescent. In delirium tremens its effect was often excellent, and quiet useful sleep was sometimes secured by it in cases in which the same result could only have been attained by the use of drugs in doses so large as to be dangerous. Alcoholism constitutes one of the most hopeful fields for its employment. The *séances* should be given twice daily for several months, and in many cases was said to become inspired with a complete disgust for drink. The opium, chloral, cocaine and tobacco habits could probably be also successfully treated in the same way; but in all these cases surveillance in an asylum was, of course, an indispensable feature of the treatment.

Masturbation and other bad habits, he continued, had been cured by hypnotism, and perhaps no more satisfactory results had ever been observed from its use than in incontinence of urine in children. Lieboldt had employed it in 77 cases, with a very large percentage of cures. The average age of the patients was 7 years, and in two of those cured there was incontinence of feces in addition to the enuresis. The results obtained were the more gratifying from the fact that many of the cases had resisted all the ordinary methods of treatment. In various rheumatic affections Bernheim and others had reported partly satisfactory results. In some chronic joint cases it was claimed that not only was the pain diminished, but that the nutrition of the joint was actually improved by the treatment. Dr. Herter thought it very doubtful, however, whether any real effect upon the joint was produced. In neuralgia much benefit could be expected in recent cases, but if the trouble was chronic there was less chance of success. Still, in some old cases of sciatica good results had been claimed, and at all events the method might often be of service in securing sleep, even if no permanent benefit could be looked for. In functional headaches it was of decided advantage, and in certain instances of migraine he had been successful in mitigating and cutting short the attacks by its aid.

At first sight it might seem that such an agency as this could have no effect upon a function like menstruation; but he said it had been practically demonstrated that in some cases not only the in-

terval between the periods, but the length of the periods themselves, could be absolutely controlled by it. The number of individuals in which such results could be looked for, however, was comparatively few. As to the employment of hypnotism in surgery as a substitute for the ordinary anæsthetics, the number of patients, with the exception perhaps of children, in whom it was available for major operations was no doubt small; especially as the anticipation of having an operation performed was extremely apt to interfere with the success of the hypnosis. On the whole, he thought its employment in this field was not to be recommended, except in cases where, for any reason, the use of anæsthetics was contraindicated. He had, however, seen a molar removed under its influence without the patient's suffering any pain or, indeed, having any remembrance afterward of the extraction of the tooth. In parturition Dr. Herter said that sufficient experience had now been accumulated to prove that hypnotism is in no wise prejudicial to efficient uterine contraction, and that it has no tendency to produce *post-partum* hæmorrhage or other bad results. At the same time he thought it was in no way comparable to chloroform in labor, and ought only to be used in those rare cases where the usual anæsthetics are contraindicated. In insomnia it could often be employed with good results, but it sometimes required months of persevering treatment to effect a cure. In cases where drugs had been resorted to it could be used in addition to the habitual remedy; the dose of the latter being gradually diminished, and perhaps finally replaced by a placebo.

Among the objections that had been raised against the employment of hypnotism he mentioned the following: 1. It tends, in certain susceptible subjects, to produce temporary mental alienation; some individuals thus developing hallucinations during wakefulness. 2. Some individuals fall asleep spontaneously; showing a tendency to auto-hypnotism. 3. Some can be readily put to sleep by any one who chooses to do so. Such bad results as these Dr. Herter thought could, for the most part, be entirely antagonized by suggestion.

In conclusion, he proposed the following general rules for those desiring to practice suggestive therapeutics:

1. Never hypnotize any subject without first obtaining his or her formal consent.
2. Always hypnotize in the presence of a third person.
3. Never give any suggestions other than those which are necessary for the patient's improvement in health.

Public exhibitions of hypnotism he believed should be prohibited by law, and the use of this agency confined exclusively to the medical profession. One advantage connected with its employment in medicine was that it does not lose its

effect by repetition. On the contrary, the subject becomes more and more readily influenced by it the oftener he tries it. From what had been said he thought it could be seen that suggestive therapeutics was not a delusion, and he said he had no doubt that before many years it would be assigned a regular position in medical service. At the conclusion of his paper Dr. Herter demonstrated on a female subject the method of inducing hypnosis.

The Chairman of the Section, Dr. W. R. Bird-sall, next read the report of a case of violent tremor of the right forearm, which he believed to be of hysterical origin, although the patient was a young man, and which was successfully treated by hypnotic suggestion. In concluding it he said he thought we were not justified in wholly disregarding a method of treatment which had already shown itself useful in many nervous troubles; though, of course, he did not mean to contend that we should by any means attempt to treat all classes of cases by hypnotism, and thus place ourselves on a level with the faith healers and Christian science people.

Dr. Osgood Mason then read a paper based on six cases of hypnotic treatment, in which he gave his deductions as follows:

1. It is of decided value as a therapeutic agent.
2. Sleep is not always necessary for the production of the greatest benefit.
3. It has the effect of equalizing the circulation.
4. It also regulates and equalizes nervous action.

Corollary.—The equalization of the circulation is the result of the equalization of nervous action.

The last paper was one on *The Therapeutic Value of Hypnotism*, by Mr. Corey, of Boston, Chairman of the Committee on Hypnotism of the American Society for Psychical Research. In the course of it he spoke particularly of the results obtained by Mr. Voisin in certain cases of insanity. He also referred to many of the affections spoken of in Dr. Herter's paper, and expressed the opinion that hypnotism was destined to prove of great service in properly selected cases in medical practice. In the latter part of it he dwelt at some length upon the medico-legal aspect of the subject, and spoke of the danger that susceptible individuals might be caused by the unscrupulous to commit criminal acts while in a state of hypnotic trance.

In the discussion that followed Dr. Kremer, after relating some cases that he had had, stated that in one instance he had considerable difficulty in arousing the patient, while in several others he found that the treatment gave rise to headache and malaise. On the whole, he said, his experience with the method, which was confined to six or eight cases of a neurasthenic or hysterical character, had not been very favorable.

Dr. C. L. Dana referred to two or three cases, and then said that it was rather a curious coinci-

dence that just at the time when the convention of the "Christian Alliance," composed of those who believed in faith healing, was treating the subject of suggestive therapeutics empirically, it should be discussed at the Academy of Medicine from a rational point of view. He said that five or six years ago, when the method of Bray was in vogue, he had paid considerable attention to hypnotism, and he had known of one subject, a young girl of nervous temperament, who was affected with convulsions in consequence of the treatment. While the method of Bernheim and Lieboldt was much less objectionable, he did not think the practical application of hypnotism was of very wide range. There were comparatively few individuals who were suitable subjects for treatment by it, and there were not many physicians who were willing to devote the time necessarily required by it. Dr. Dana thought the so-called faith cure and Christian science should be prohibited by law, and expressed his opinion that it was better for a person to remain ill rather than to be cured by such agencies, because they tended to produce paresis of the will and eventually bring about a certain amount of volitional degradation.

Dr. Herter said, in reply to Dr. Kremer, that he had never found any difficulty in arousing a patient from the hypnotic sleep, although he had seen the method tried in over 100 subjects. The only exception was in an individual who had been in a spontaneous condition of trance previously. He did not think this a valid objection to hypnotism, and as to the headache and malaise referred to, he believed these could always be prevented by suggestion before allowing the patient to waken. He agreed with Dr. Dana as to the bad effects of Bray's method with the bright light, which had been known to give rise to epilepsy and convulsions; but said he was not aware of any evil results having been noted from the method now employed. He had never noticed any depressing tendency about the treatment, and, as far as his experience went, he believed it was comparatively easy to hypnotize quite a large proportion of individuals in the community.

MISCELLANEOUS.

DIPHTHERIA SPREAD BY CATS.—Domestic animals have often not only been suspected but found guilty of spreading infection. In his report on the recent sustained prevalence of diphtheria in Enfield, Dr. Bruce Low of the medical department of the local government board incidentally states that during the continuance of the epidemic cats were observed to suffer in considerable numbers from illness, and in December, 1887, and in January, 1888, there was a large mortality among those animals, so much so that the attention of the dust contractor was directed to it. He stated that never in his previous experience had he seen so many dead cats in the

dust heaps. Some households seeing their cats ill, destroyed them. Though there were no known cases of diphtheria occurring in the practice of the veterinary surgeons at Enfield, yet they saw many cases of "influenza" at this time among animals. The following is an illustration of the possible connection between diphtheria in children and in cats: A little boy was taken ill with what turned out ultimately to be fatal diphtheria. On the first day of his illness, the cat, which was in the room at the time, licked the vomit on the floor. In a few days (the child meanwhile having died) the animal was noticed to be ill, and her sufferings being so severe and so similar to those of the dead boy the owner destroyed her. During the early part of its illness this cat had been let out nights in the back yard, as usual. A few days later the cat of a neighbor, who lived a few doors further off was noticed to be ill. It had also been out in the back yards at night. The second animal, which, however, recovered, was the pet and playfellow of four little girls, who, grieved at the illness of their favorite, nursed it with great care. All four girls developed diphtheria, the mother being convinced that they got it from the cat; and, indeed, no other known source of contact with infection could be discovered. It is easy to imagine cats catching infectious diseases like diphtheria when we remember how often milk and other unused food from the sick-room is given to the cat, or by some people thrown out in the back-yard for the benefit of their neighbors' cats if they have none of their own. It is a frequent occurrence to see children carrying cats in their arms, and even kissing them. It is obvious that if the cats were ill with diphtheria the children, under such circumstances, would almost inevitably contract the disease.—*London Sanitary Record*.

ACTIVITY OF THE SCARLET-FEVER POISON AFTER A YEAR.—Dr. J. Brook, Surgeon U. S. Army, of Fort Monroe, Va., communicates the following case: "A girl aged about eight, living at this place, was some months ago attacked by scarlet fever, the disease running a typical course. For a long time no possible source of contagion could be discovered. The child had not been absent from home, had been with no one lately exposed, and no other case was known to exist anywhere in the vicinity. Subsequently I learned that one of the house-servants had nursed a case of scarlet fever in a distant city just about a year before. After the case terminated she packed some of her things, including some clothing then worn, in a trunk, and left the place. A year later she had the trunk sent to her here, opened it, and took out the contents, the little girl being present and handling the things. Very soon after the latter was attacked, as stated.

"As fixing the period of incubation, it would be interesting to know precisely how many days passed from the time the trunk was opened until the disease appeared; but I was unable to determine that period satisfactorily."—*The Medical Record*.

INQUESTS OF DEATHS FROM PREVENTABLE DISEASES.—At the Paddington Vestry on Tuesday last a resolution was submitted from the Sanitary Committee, setting forth that several cases of death from preventable diseases having been reported to them under circumstances which suggest that the cause has been defective sanitary arrangements, and that the Committee is of opinion that in all such cases application should be made to the coroner to hold an inquest as to the cause of death, and recommending that a copy of the resolution be sent to all the vestries and district boards of the metropolis. It was further suggested that copies should be forwarded to the medical practitioners in their respective districts. Dr. Danford Thomas approved of holding an inquest where there was evidence of gross sanitary neglect.—*British Medical Journal*, Sept. 22, 1888.

DR. E. MILLER REID has recently been elected to the Chair of Physiology and Hygiene in the Baltimore University School of Medicine.

DR. F. R. CAMPBELL, a talented physician and writer of Buffalo, died of typhoid fever on September 14, at the early age of 28 years.

DR. HARVEY JEWETT, of Canandaigua, N. Y., died on September 4, aged 79 years.

Official List of Changes in the Stations and Duties of Officers Serving in the Medical Department U. S. Army, from October 13, 1888, to October 10, 1888.

Capt. Edward T. Comegys, Asst. Surgeon, is relieved from duty at Madison Bks., New York, and will report in person to commanding officer, Ft. Bayard, N. M., for duty at that post, relieving First Lieut. William D. Dietz, Asst. Surgeon.

First Lieut. Dietz, on being relieved by Capt. Comegys, will report in person to commanding officer, Alcatraz Island, Cal., for duty at that post, reporting by letter to the commanding General Dept. of California. Par. 18, S. O. 240, A. G. O., Washington, October 15, 1888.

By direction of the Secretary of War, the following named officers of the Medical Department will report in person, on October 23, 1888, to the President of the Army Medical Examining Board, Army Building, New York City, for examination for promotion: Capt. John de B. W. Gardiner, Asst. Surgeon; Capt. William C. Gorgas, Asst. Surgeon; Capt. C. N. Berkeley Macauley, Asst. Surgeon; First Lieut. W. L. Kneudler, Asst. Surgeon; First Lieut. Edgar A. Mearns, Asst. Surgeon. Upon completion of their examination the officers named will rejoin their proper stations. Par. 1, S. O. 239, A. G. O., Washington, D. C., October 13, 1888.

Capt. Benjamin Munday, Asst. Surgeon, is relieved from duty at Jefferson Bks., Mo., and will report in person to the commanding officer, Ft. Sisseton, Dak., for duty at that post, relieving First Lieut. John L. Phillips, Asst. Surgeon, and reporting by letter to the commanding General, Dept. of Dakota. Par. 11, S. O. 242, A. G. O., Washington, October 17, 1888.

First Lieut. Phillips, on being relieved by Capt. Munday, will report in person to the commanding officer, Ft. Lyon, Col., for duty at that post, reporting by letter to the commanding General, Dept. of the Missouri. Par. 11, S. O. 242, A. G. O., Washington, October 17, 1888.

Official List of Changes in the Medical Corps of the U. S. Navy for the Week Ending October 20, 1888.

Surgeon A. F. Magruder, ordered to Marine Bks., Washington, D. C.

Asst. Surgeon E. P. Stone, detached from the "Richmond" and to the "Minnesota."

Asst. Surgeon J. F. Keeney, detached from the "Minnesota" and to the "Richmond."

Asst. Surgeon A. M. D. McCormick, detached from the Bureau Medicine and Surgery, and to the "Vermont."

Surgeon A. M. Moore, detached from naval station, New London, Conn., and to the "Kearsarge."

P. A. Surgeon A. A. Austin, ordered to naval station, New London, Conn.

Official List of Changes of Stations and Duties of Medical Officers of the U. S. Marine Hospital Service, for the Two Weeks Ending October 20, 1888.

P. A. Surgeon S. T. Armstrong, granted leave of absence for sixteen days. October 17, 1888.

Asst. Surgeon R. M. Woodward, when relieved at Marine Hospital, Boston, Mass., to proceed to Marine Hospital, Chicago, Ill., for duty. October 12, 1888. Granted leave of absence for thirty days. October 17, 1888.

Asst. Surgeon A. W. Condict, relieved from duty at Marine Hospital, Chicago, Ill.; ordered to Marine Hospital, Boston, Mass. October 12, 1888.

THE SCHOOLROOM A FACTOR IN THE
PRODUCTION OF DISEASE.

Read in the Section on State Medicine, at the Thirty-ninth Annual Meeting of the American Medical Association, May, 1888.

BY J. A. LARRABEE, M.D.,
OF LOUISVILLE, KY.

This is the first time in the period of my membership in the Association that I have had the honor to appear before your Section. I am satisfied that this affliction has been put upon you by mistake in making up the schedule for the last year. Most of my time is spent in the Section of Pediatrics. It may be truly said that any doctor who has practiced his profession for a score of years has in that time become a true philanthropist. That he will always be found to take the greatest interest in whatever concerns the welfare of the human race. Obedient, therefore, to your call, with the desire expressed, I have hastily prepared a few words upon a subject with which I am brought into daily contact. A subject which not only concerns the present, but also the future health of children.

It is a fair general estimate that one-third of the lifetime of every educated person is passed in the schoolroom. It follows, therefore, that the location, construction and surroundings are all matters of importance. It is gratifying to know that a great advance has been made in cities in these particulars. If, however, education means the development as well as the training of the mind, there is still much to be desired. Every schoolhouse should be located with a view to the free admission of sunlight and fresh air. In Switzerland the summits of small hills are selected as the proper location. The building should be made attractive to the eye in every possible manner. Ocular impressions are powerful educators. Manufacturing corporations in our eastern cities and villages appreciate this as bearing not only upon the physical health, but also the happiness and contentment of their operatives. The immense cotton factories which one sees in New England present the appearance of palaces, surrounded as they are by parks, lawns; with fountains and rare and beautiful flowers. I have

been told that the proprietors are abundantly repaid for this great outlay of money in the moral and physical welfare of their tenants. But the operatives in mills and workshops ought not to be compared with children. Men and women can withstand the effects of vitiated air and unhealthy surroundings for years without serious danger to their health. The susceptibility to disease from such causes is in inverse proportion to the age of the individual. The inside of the schoolroom should also be made attractive. Instead of blank walls there should be paintings, historical and instructive. Pictures are wonderful educators.

Ventilation, although universally acknowledged to be of the utmost importance in maintenance of health, is still very faulty. The hot-house plan prevails. The fault is not so much with the teachers as with the home. Children reared in stove or furnace heated homes are chilled at a temperature of 66° F. in the schoolroom. This temperature is quite sufficient if begun in the autumnal commencement and kept up all winter. The desire for more heat arises from over-exhaustion and depletion by brain-forcing study, or want of proper exercise in the open air. The cubic space of air to each scholar varies in our schoolrooms from 200 to 300 feet. Prof. Kedzie fixes 300 as the maximum limit for health. This would necessitate an entire change of air about every fifteen minutes to prevent re-breathing. An ordinary schoolroom would require 175,000 cubic feet of air per hour. There can be no doubt that this amount of fresh air is needed. How to obtain such ventilation without exposure to draughts must be a perplexing question to every teacher.

The top and bottom protection slide, or better, the middle-joint sash ventilator ought to be enforced. The science of respiration has demonstrated that the largest amount of carbonic acid compatible with life is 7 parts in 10,000. These estimates are made in mines, where the dimly-burning candle and the miner's lamp are extinguished. When, however, the carbon dioxide present is due to overcrowding a much smaller amount becomes oppressive. In closed churches and theatres a drowsy audience is not always the fault of preacher or actor.

The schoolroom is a propaganda of contagion. The opening of schools in the autumn is the sig-

nal for the outbreak of contagious diseases rekindled from the still smoking embers of the last year's epidemic. There is no remedy, save in the formulation of discreet rules and their rigid enforcement by the authorities. Children come to the schoolroom from every sort of home, the unclean and the clean. Those wearing soiled clothing mingle with the neat and tidy. No schoolroom should have an odor, and no teacher should be employed whose olfactories are at all blunted. There is a prison smell, a hospital odor, a lying-in odor, etc., and there is a school odor, and wherever these exist there is disease and death. Right here is the place to begin the practical instruction in hygiene. Impressions made upon the growing mind are lasting for good or evil. It is very hard to convince people of the necessity of caring for their bodies after they have formed habits of uncleanness. This is the reason that we meet with so much opposition in enforced sanitation. We shall never accomplish much in public hygiene until we commence with the school room. Wash-rooms, clothes-rooms, shoe-rooms, are necessary attachments to every schoolroom.

School Headache.—This is one of the most common complaints among pupils. The cephalalgia is frontal—often supra-orbital. There is always a slight elevation of temperature—and anorexia. Oculists have written upon the frequency of such headaches, and attribute the attacks to overstrain of the eyes. As a result we see boys and girls below their teens *wearing glasses*. Such cases are very common in my practice and I have almost invariably found them due to constipation, which may be attributed to sitting, but more especially to inattention to the calls of nature. The evacuation of the cæcum depends very much upon the contraction of the neighboring muscles, the psoas and iliacus, as in walking. School constipation is of this character, and is not unfrequently attended by typhlitis and circumscribed peritonitis. Females are proverbially prone to constipation with acid eructations. In more advanced schools, colleges and seminaries neglect of the bowels causes at least two-thirds of all illness. The most apparent sequence is a gradual poisoning of the system by retained excrementitious matters constituting a condition properly called stercoræmia. The subjects of such blood poisoning present a sallow anæmic appearance with a languor marked in every movement. But the consequences of school constipation, besides producing headache and lassitude, fall elsewhere with the female. The frequency of uterine displacements in virgins is recognized by gynecologists. We instinctively shrink from the treatment of such conditions, while there is every reason to believe they exist and that their existence is largely due to retention of urine and feces beyond a reasonable limit. We live in a day of specialism, and the demand is for more. Eye doctors, nerve doctors, pile doc-

tors, and womb doctors, draw their patrons most largely from the schoolroom. Grandmothers peer curiously over their spectacles when informed that their granddaughters are subjects of diseases which only married women are supposed to have and seldom had in their day.

Eye Troubles.—The frequency of hypermetropia and astigmatism is not only noteworthy among pupils of our public schools, but also myopia, due to prolonged study. The statement that nine-tenths of all cases of myopia originate from the schoolroom is startling. This defect is practically unknown among the uneducated. It is in consequence of overstrain. The deformity once acquired is permanent and renders the subject unfit for many of the duties of life. Oculists, I believe, consider the disease progressive in character, originating in childhood, never after the age 20 years. Ribot says the number of short-sighted persons must necessarily increase in any nation devoted to intellectual pursuits. Germans are proverbially near-sighted. Dr. Loring, in a paper upon this subject, makes the statement that 62 per cent. of the public school pupils in Germany are short-sighted. A faulty construction of the windows in regard to the admission of light may cause a preponderance of such cases to obtain in a certain school. It is probable that this deformity may become inherited.

Consequences of Overstrain not the same in both Sexes.—So long as sexual differences remain unappreciated, girls participating in rude, boyish sports, school study and restriction may be considered to affect the sexes equally. This period of life, always too brief, is much shorter in cities than in the country—a circumstance largely due to that oft' forgotten but nevertheless potent educator, the "street school." The period of more active growth and development corresponds to the age at which the most arduous tasks are required of the mental faculties. The physical perfection of woman demands at this period plenty of exercise in the open air and free supply of blood to the pelvic viscera. Instead, however, the blood is used to supply the brain, and the generative organs suffer. The inexorable laws of society demand an early finish to the education at any cost. The latter is acceded to, and the consequence falls like a withering blight upon the tenderest buds of our hope and promise. There are few, if any, female schools where there is any relaxation of discipline or study on account of the occurrence of menstruation—and this despite the knowledge that mental application at this time results in hysteria, and often in mental aberration, or the complete arrest of the menstrual function. Here, indeed, is the axe laid at the root of the tree, and the foundation broad and deep for future invalidism and the work of the gynecologist. Another phase of this question is already attracting the attention of thinking

men in the medical profession; a question assuming National importance; it is the sterility of highly-educated women, who, when girls in their teens, have been subjected to the ordeal of collegiate examinations. It has also been observed that of those who conceive, the mortality in child-bearing is exceedingly high. We are rapidly losing our National identity. It has been estimated that the State of Massachusetts will soon become depopulated of American children, notwithstanding her 70,000 old maids. Dr. Moore, following the inductive reasoning of Herbert Spencer, makes the statement that "America must in future look to Europe for her mothers." Sociologists and biologists have shown that motherhood decreases with high intellectual cultivation.

Just here I am constrained to say something in regard to the fault in our educational system itself. Children are taught more and know less than in our grandfathers' days. Book knowledge is overestimated and practical reasoning undervalued—a fault which extends to our colleges and medical schools. A blind allegiance to the so-called authorities leads to effeminacy of thought and destroys individuality. The failure of our brightest collegiate graduates to obtain lucrative employment is certainly suggestive of a want of practical education. The constant struggle in the various school grades is to pass rather than to know, and, as Huxley puts it, "outraged nature takes her revenge," they do pass and they don't know. The credulity of many educated people, and the readiness with which they seize upon the most palpable frauds, is a sad comment upon our schools of philosophy. A few years ago it was spiritualism, then blue glass, and now Christian science. Think of a young mother and her infant perishing from causes which even a trained nurse or a midwife could have easily prevented. She was a woman of culture and died a martyr to Christian Science, a sect to which she and her husband belonged. Facts which have been recognized from the beginning of science are isolated and built into sects. How long will it be before we shall resort to songs and incantations for the restoration of the sick, as did the ancient Greeks?

Chorea (St. Vitus' Dance).—Chorea, with all its train of consequences upon the growing brain and nervous system, is among the diseases produced by overstrain in the school-room. A discussion of the relation between chorea and rheumatism would not be germane to the subject under consideration.¹ In a former paper I have attempted to show that the exhausted nutrition of growth, plus brain, work produces both, and also that the two diseases are controvertible, if not indeed identical. Here, as elsewhere, overstrain is not equal in consequences upon the sexes. Girls

are more prone to chorea. When my clinic for diseases of children was held in the fall and winter months, cases of chorea were only occasional luxuries for a lecture subject. Since, however, this clinic has been made to include the spring and summer months, there is rarely a lecture day without a new case of St. Vitus' dance. Nine cases typical of the disease were present at the dispensary in a single week; of these seven were girls and two boys. All were pupils in public schools and were bright and ambitious scholars, who shed tears when told that the treatment would include a complete cessation of school work. Besides these, I select from my notes of private practice a few cases to illustrate the cause.

L. G., a bright girl of 13, growing rapidly, attacked during Christmas week. The involuntary movements, at first unilateral, rapidly involved the whole body, causing her to fall. Studies in school were history, geography and spelling to memorize, reading with definitions, arithmetic mental, arithmetic practical, drawing, grammar, music and composition. Time of study in school-room, including recitations, five and one-half hours, necessitating three hours' hard study at home every night excepting Sunday. She was at the head of her class, and talked in her sleep of her studies.

A. H., æt. 17. Chorea severe, general, but more marked on left side. Hardly able to carry her books to and from school. Same grade in different school. To these, from the same school, could be added four others ranging from 12 to 16 years of age. Three of these developed cardiac lesion, one died of peri- and endocarditis, and while the subject of chorea developed polyarthritis.

The difference between voluntary and forced learning is the difference between mental strength and mental debility. All of these children will be intellectually as well as physically weakened by the nerve-storm through which they have passed. The difference between partaking of food when we have an appetite and crowding it into a stomach already satiated is dyspepsia. There is a mental as well as a physical dyspepsia, and these over-taught school-children are the victims. The power of concentration of thought is feeble in the child. "The child's will is the wind's will," says Longfellow—and we see in this a wise provision of nature, as beneficial to the growing brain as is motion to the limbs.

The physiological law is that any work in excess of the power of the system adds nothing whatever to the desired result. If a child's capacity to learn is exhausted in two hours, there will be no gain by studying five hours. It has been ascertained that the longest period of thought that can be concentrated upon a single proposition with advantage is fifteen minutes. The astonishing progress made by pupils in our night schools has been a matter of comment among teachers.

¹ "Acute Rheumatism of Childhood," Kentucky State Medical Society, 1879.

Can it be that the flickering gas or lamplight, and the depressing influence of night, are found conducive to learning? Certainly not. But the importance of a suitable admixture of physical labor is so great that even these serious objections are overcome. England has a system by which 100,000 children are able to get from two and a half to three hours' schooling in the twenty-four. This is known as the "half time law," and it has been found that such scholars compare favorably in attainment with those who attend the regular all day sessions.

Consumption Favored by School Discipline.—There is no point better settled in pulmonary therapeutics than the necessity of development of the apices of the lungs. Whatever of truth, if any, shall be found to attach to Koch's microbes, the fact remains that consumption may be prevented by expansion of the top of the lungs, that this is always the favorite seat of tubercular deposits, and that, conversely, whatever tends to lessen the capacity of the apex tends to produce the disease.

The position of the growing child bending or stooping over a desk in school for six hours a day effectually prevents such development. Shoemakers, bookkeepers and tailors are found more than other trades in the consumptive ranks, and it is in the main due to this cause. The respiration becomes insensibly more and more shallow. In the child the shoulders are approximated more readily, and the lung actually folded in upon itself.

This matter of the expulsion of the residual air in the lungs is a too much neglected point in therapeutics. The introduction of vocal music in our common schools will result in great good. Dr. Rush declares that the German people are largely indebted for their exemption from pulmonary consumption to the strength and volume which their lungs acquire in the practice of vocal music. It would be well if, at the end of each study hour, classes were obliged to stand and sing while fresh air is being admitted to the room.

In conclusion, Mr. Chairman, let me say that the evils of the school-room are not primarily the fault of the teachers, who are always overworked and always underpaid. The fault is in the people and the needed reform must commence with the people. A complaint was made a few years ago that shoemakers were ruining women's feet by making high-heeled and contracted shoes, to which complaint the craft very aptly replied, "We would not make them so if they were not demanded." Let the public demand instruction in natural laws, mental and moral philosophy, and hygiene. Let the old Greek apothegm be hung at the entrance of our institutions of learning. Physiology and hygiene should be taught in all schools and all grades. At present, if at all studied, it is reserved for high schools and colleges, where it is usually finished in a few weeks. Cæsar said to the soothsayer, "What concerns our-

selves must be last," and the sentiment cost him his life. It has cost many lives since.

It is as important to know that bile ducts open into the intestines as it is to know that the Lena River flows into the Arctic Ocean. It is as important for a girl to know how long it takes beef-steak, pickles and slate pencils to digest in a stomach as it is to know how long it takes the light of one of the fixed stars to reach our planet. Let the course of study be made different for the sexes. Lectures in domestic economy might be substituted for political economy, so that when the *ultima thule* of their ambition shall be reached they may reign queen of the household and remain queen of hearts. How many physical and mental wrecks, which now lie at the very threshold of manhood and womanhood, might be prevented by proper instruction. Children are educated more on their way to and from the school-room than they are within its walls, and this kind of education usually sticks, because it is obtained from observation. The first evasive answer to the question of the origin of themselves is the first false step in the child's future career. His innocent questioning of natural laws is silenced with such an emphasis as to awaken a latent curiosity. Is it any wonder that he should take his question to the great street school, with its vulgar jest for an answer? And is it a wonder that he should regard his teacher in the alley as a superior oracle whom he will consult on future occasions when such questions arise? Let us have such a blending of the physical with the mental development that brain work will not tire. Then the school-house will be the promoter of health rather than disease. There is no reason why study should not strengthen the mind as well as that the steady blows of the blacksmith strengthen his arm, if properly conducted. Then, and then only, may we hope to see more of that exceptional attainment, a sound mind in a sound body.

DR. LINDSLEY, of Tennessee: I have listened attentively to this paper, and with much interest. Since 1855 I have been connected with the Board of Education of my State, and have visited school-rooms all over the United States, talking with the superintendents and professors. The subject of Professor Larrabee's paper is of paramount importance, relating as it does to the millions of children attending our schools. There are two important points which occur to me in connection with it: 1. Medical men must arouse public attention to the necessity for paid medical inspectors. 2. I would put no text-books of hygiene in the schools, because the masses do not get this education. The majority of children leave the schools before reaching the higher classes where this subject is taught. Hygiene should be impressed upon them by every feature of their environment.

DR. HIBBERD, of Indiana: I agree with Dr.

Lindsley in the utter impossibility of teaching children in primary schools enough physiology to be of utility. There are many who are grandfathers who do not know what it is absolutely necessary to teach. Teach youth to observe, and what things they should observe. The trustees of schools understand the necessity for air, light, etc., but they cannot get the money to provide them. Every school-house in the land should be situated so as to face the best direction of the compass, having air and light in abundance, but it will cost a great deal of money.

We must recognize that all children are not exactly alike in their capacity for receiving education; and the present methods are faulty in teaching all children on the same plan. Due regard must be paid to mental and physical variations, and sound minds and bodies cannot be had until this is recognized.

DR. HAMILTON, U. S. Marine Hospital Service: The question of eyesight in school-children is one of particular interest to me, and foreign journals have devoted a great deal of space to the consideration of this question during the past year. Dr. Larrabee referred to the majority of German children being myopic; I think this is due to the employment of the old black letter. German medical text-books are printed in Roman letters; but for political reasons the black letters are generally used. I certainly agree in the necessity for school inspectors; and the first thing they should do would be to examine the text-books, the paper of which is often inferior, and the printing but little better. Another feature demanding improvement is the sitting arrangement of a school-room. We all know the country school-room with its four rows of desks, and windows on either side of the room, which imperfectly light the middle rows of desks.

DR. VAUGHAN, of Michigan: While I agree with the paper, I do not believe that all defects in eyesight in school-children are attributable to the school-room. If you enter any family room at night, the father and mother will be found sitting on either side of a table on which the light is, and the children are allowed to sit anywhere. I believe more harm is done our young girls by sitting up late at night at parties and dances, than by all the alleged confinement in the school-room. Dr. Larrabee did not refer to the stairs, which are usually selected as one of the fertile sources of disease in young girls; but if you watch a woman go upstairs, she does it with her body bent forward and swinging from side to side, instead of going upstairs erect. I believe the German method of the climbing cure might be employed advantageously in some of these cases.

I am not prepared to state how it is in other States, but in Michigan most children are better situated at the school-house than at home. Farm houses, as a rule, are far from being good sanitary

types. I do not believe that any necessary money would be withheld to secure first-class schools. The ignorance of teachers on hygienic matters seems to me to be the primary evil.

DR. HIBBERD, of Indiana: I wish to complete an omission in my remarks. I believe with Dr. Vaughan that the fundamental education should be with the teacher. But the architect must also be remembered. This gentleman usually puts his efforts on the adornment of the exterior of the building, and the interior is suited to this. We cannot get architects to give sufficient attention to the interior of these buildings, because it is their aim to produce handsome work.

DR. LINDSLEY, of Tennessee: I should like to ask Dr. Vaughan if the State Board of Health of Michigan has not acted as inspector of schools; and if its creation has not permeated the school system with its influence?

DR. VAUGHAN: The plans for school buildings must be approved by the State Board of Health.

CATARACT EXTRACTIONS, WITH ONLY THE EYE OPERATED UPON CLOSED BY ADHESIVE STRIPS.

THE OTHER EYE LEFT OPEN FOR THE GUIDANCE OF THE PATIENT.

Read in the Section on Ophthalmology, at the Thirty-ninth Annual Meeting of the American Medical Association, May, 1888.

BY JULIAN J. CHISOLM, M.D.,

PROFESSOR OF EYE AND EAR SURGERY IN THE UNIVERSITY OF MARYLAND, AND SURGEON-IN-CHIEF OF THE PRESBYTERIAN EYE AND EAR CHARITY HOSPITAL OF BALTIMORE CITY.

At the last meeting of the American Medical Association, June, 1887, I read a paper on the advantages of the isinglass plasters as the only lid dressing after cataract extractions, and the keeping of patients in moderately lighted rooms instead of the dark ones. I also stated that for some weeks I had made bold to leave one eye open for the guidance of the patient during the entire after-treatment. That this method of after-treatment would add immensely to the comfort of the patient, was evident to all; the only question was as to its safety, for the great results to be finally secured. Since that time, another year has passed, and with the twelve months' experience added, much more confidence can be expressed in the advantages of the method, revolutionary as it seems.

In my "Hospital Cataract Case-Book," every case of cataract extraction is entered. With the pure and simple senile cataracts in healthy patients, are put those of traumatic or inflammatory origin with iritic, choroidal and glaucomatous complications; all appear. Heretofore, in making up my reports and in tabulating the amount of vision secured to patients, a cataract extraction that was in every way a perfect success, the after-treatment having been accompanied

by no inflammation whatever, leaving the patient with a clear cornea and good pupil, was counted a failure because of nerve atrophy or extensive central choroidal or retinal changes, now rendered clearly visible by ophthalmoscopic examination through a transparent vitreous. As in the percentage of no restoration to sight these cases unjustly appear as failures in the general summing up after cataract extractions. In the list which I now present I will put only those of uncomplicated cataracts, so that proper comparison may be made between the methods of light afterdressings and treatment in light rooms which I strongly recommend, and the heavy dressings and dark rooms which others use.

In this list, culled from my case-book for the year ending May 1, 1888, I find seventy-four cataract extractions, dressed by a single strip of adhesive plaster over the eye operated upon only, the other eye being left open. Of these eyes so simply dressed none were lost. There was not a single case of corneal sloughing. In every case the cornea was clear, and in only two cases were the pupils closed by iritic adhesions, rendering an iridectomy in the future needful for the restoration of vision. In all of these cases the biniodide of mercury solution was freely used as an antiseptic during all steps of the operation.

My successful cases are not all V. $\frac{2}{10}$. Many of my hospital patients are drawn from distant regions, poor parts of the Southern country, and have not the means to pay for a second visit to Baltimore to have the secondary operation performed for the removal of capsular thickenings. We all know that these capsulotomies must enter largely into advancing cataract patients to the higher degrees of vision. Most of my cases are farmers from the States of Virginia, North Carolina, and Maryland. If they can see to read ordinary print and attend to their farm duties it is all that they desire. The improvement is so immense upon the no seeing with matured cataract, that they are perfectly satisfied with the results as secured by a primary operation. In their anxiety to get home as soon as the eyes become strong enough to stand ordinary light, I cannot retain them over a fortnight under observation. At this stage of progress after cataract extraction, vision, as we all know, is by no means the best. I again state, that if my cases when I dismiss them, at the end of two weeks never to see the majority of them more, must be accepted on the status of V. $\frac{2}{10}$, I will contrast unfavorably with the operators in the largest cities, whose cases may frequently return to them for examination and after-treatment for many months, until time, secondary operations, the careful adjustment of lenses, with the correction of such astigmatism as remains after the operations, will put their eyes in the best condition to exhibit the high degrees of excellence which cataract operations will finally bring about.

The point which I desire to make, is this, in answer to the following question: Is the exposure of one eye, and the light dressing of the other eye by a piece of adhesive strap, after cataract extraction, conducive to inflammation? My experience answers very positively, that it does not. It matters not what our preconceived notions are. It is so easy to theorize as to the necessity of adjusting compresses for the support of the whole cornea, so that all parts will be equally pressed upon. That absolute rest of the eyes is required for the healing process to be perfected. That the movements of one eye will necessarily cause the closed one to move to like extent, and that this frictioning of the wounded cornea against the lid must bring on inflammation. These opinions may be very satisfactory to those who always close up both eyes, and put their patients to bed, where they are kept on their backs for days in the dark. But if they will adopt the method which I use of closing up one eye properly, with a piece of isinglass plaster, that eye is as absolutely safe against all jarring as if a cut finger were dressed in similar manner. By this method, which in no way can disturb the nice relations which the eye ball and lids have always sustained to each other, there is nothing to friction injuriously against, even when the eye does move in its relations with the exposed one.

If an ophthalmic surgeon in his hospital work will try the methods honestly in an equal number of simple senile cataracts, his personal experience will soon show him the advantage of this simple treatment. Let him take a number of cataracts, as they may come in from week to week for surgical treatment, each alternate one to be operated upon in his bed, with both eyes closed by compresses and bandages, and kept absolutely quiet in a dark room with all the restraints that are usually imposed. Again, let each alternate one be operated upon in front of a large window, upon a convenient operating table, then close the eye properly with a piece of isinglass plaster one and one-half inches long and one inch wide, see that it is so thoroughly adjusted that the lids are made into one piece as it were, for the perfect support of the divided cornea. Leave the canthi free from the covering to permit of the escape of secretions, and for the introduction of drops by capillary action, if they be needed, without disturbing the adhesive dressing. When the plaster is dry and the lids closed let him get off from the table and walk to his moderately lighted room, guided by the eye which has been left open. When there, let him follow his own inclination to lie on the bed or sit in a chair. He will undress himself at bedtime and dress himself in the morning, eating his regular meals, and enjoying the sight as well as the conversation with friends. Then remove the strap from the one, and the badge from the other simultaneously. If

the cases have been operated upon with equal care antiseptically, the operation being in all cases equally smooth, the surgeon will find himself at the end of two weeks with twenty cases of cataract extraction equally free from inflammatory complications, and that is all that the most anxious operator can wish for.

During the week of treatment, at the daily visits, the surgeon must have noted the cheerfulness of the patient who had one eye opened and who had enjoyed the pleasant companionship of friends, when contrasted with the gloomy doubts and the shaken faith of the blind-folded one, who could not help inquiring how long he must endure this darkness. We will say nothing of the lighted candle which was brought in by the nurse to keep the surgeon from colliding with the table or other bed-room furniture. Then contrast the condition of the eyes at the time the strap and the bandage are removed. The one in the lighted room looks at you and you at him, as you have done daily. You have seen the adhesive strap day by day free from secretions and retaining its adjustment. You now see the newly exposed eye singularly devoid of redness and of weeping. It stands the light wonderfully for one so long closed, because the one always opened has preserved the closed one from the acquired sensitiveness engendered by darkness. As the candle is brought for the inspection of the eye released from the dark bandage, the injection and weeping, incumbent on the exposure after the week of night, do not surprise us, for we are accustomed to see it in every case thus treated.

Follow the two classes of cases up to the end of the two weeks, to the day of dismissal. The one treated by the bandage has never been for a moment without the protection of dark smoked glasses, and cannot go for a moment without them. The one treated by the adhesive strap with one eye opened had never had the smoked glasses on, and has never felt the want of them. One cannot bear the light, the other is not aware of its presence, and only puts on smoked glasses as he goes out on the street because he is told to put them on.

In the March number of the *Archives of Ophthalmology*, 1888, Dr. Oliver Belt, my resident physician at the Presbyterian Eye and Ear Charity Hospital of Baltimore City, has published a paper written some months since, on the result of one hundred cases of cataract extraction treated by the isinglass plaster, in light rooms and without restraint. Some, the earlier cases, with the closure of both eyes, and the last half of the series with one eye alone closed. These were taken as they appear in the case-book of the hospital, and as he very properly says, some of them with glaucoma, nerve atrophy, and other fundus complications. In his table it is seen that eighty-three of the one hundred had good vision,

seven had improved sight; in five there was no improvement from causes, fundus troubles easily appreciable after the cataract was extracted, and five were failures. Among the five failures one was from purulent contagion, panophthalmitis, a misfortune or accident that would have occurred under any kind of after-treatment. The second was in an old feeble man of 91 years of age, who was willing to take the risk in his desire to see. The third patient left the hospital for her city home seeing well. In getting from the street car to her house door she was caught in a summer shower, and from wet clothing and exposure the eye took on inflammation and was lost. Most surgeons would have ignored this accident, as she was dismissed from the hospital with good sight. I counted it as a loss for final success. Two alone remain as inflammatory complications, belonging to the operation of cataract extraction, and the treatment, a loss of 2 per cent.

In the same volume of the *Archives of Ophthalmology*, for March, 1888, Dr. H. Knapp reports a series of cataract extractions without iridectomy. He states how carefully he has used antiseptic precautions, avoiding all unnecessary movements, as tending in his opinion to the displacement of the iris, and how he has bandaged with care both eyes. He contrasts his method of dressing with the simpler method. Thinks Chisolm has gone too far in simplifying the after-treatment of cataract extractions, and then compares the final results in his carefully selected series of simple senile cataract extractions with the table from Dr. Belt's report of my hospital work, in which complicated as well as simple cases are mingled together. He closes this part of his paper with this statement: "The superiority of Dr. Chisolm's bandage is not borne out by his statistics. Five per cent. of loss and 5 per cent of no vision, is below the average success of experienced and skilled operators to the front rank of whom we all know Dr. Chisolm belongs." This is an unfair contrast, the more especially as Dr. Belt has explained in his paper how these cases were failures in seeing, even when no inflammatory complications had arisen during the after-treatment of the cases; and how an ophthalmoscopic examination showed glaucoma, nerve atrophy, or central choroidal patches. If the operation of cataract extraction, even in these cases, had not been in every way successful how could the ophthalmoscopic investigation have been afterwards made. Sight was not restored, but that was not the consequence of an unsuccessful cataract extraction.

I here repeat what I had mentioned in the beginning of this paper, viz: that from May 1, 1887, to May 1, 1888, I had made seventy-four simple uncomplicated cataract extractions under the simple dressing of one eye closed with an adhesive strip, keeping the patient in a lighted room, and avoiding all restraint in his move-

ments and in his surroundings. Of these cases I have not lost a single eye. In only two did inflammatory closure of the pupil occur, which will require a secondary operation for the restoration of vision.

I have now had two years' experience in this simple dressing of eyes after cataract extraction. For the past year I have left one eye open in all cases. I have not used dark rooms. I have not operated on the patient in bed, but always in the operating room, before a large window, and upon a firm narrow table. In every case the patient has walked from the operating room to his chamber, guided by the eye left open when it possessed vision enough. In no case was the patient put to bed unless he desired it, and every freedom of movement was permitted. In no individual case have I seen any trouble that I had not met with before, when I was in the habit of using careful bandaging, dark rooms and all the restraints, which many still impose.

As to the final success of the operation, I have always thought that nine-tenths of the dangers were incurred during the operation. If the entire manual has been satisfactorily, or as we now say smoothly done, under antiseptic precautions, it makes but little difference how the case is afterwards dressed, success is most likely to crown the skillful operation.

I know that eyes get well under bandaging and bed confinement for I have individually had the experience in hundreds of cases. I know that eyes after careful cataract extractions will get well without inflammatory complications, under a light adhesive strap dressing of the eye operated upon only, the other being left open for the guidance of the patients. Whether the patient is put to bed and kept quiet or whether he is allowed to sit up and walk about, whether he is undressed or is allowed to dress himself, whether he is made to keep silence or is allowed to talk, whether he is kept in the dark or is permitted to enjoy the pleasure and comfort of daylight, whether he is surrounded by no restraints or is rigidly deprived of all liberty. In all of these diametrically hostile conditions of after-treatment of cataract cases, those carefully and judiciously operated upon will have sight restored and all in like ratio. Then let us show mercy and consideration for the comfort of those who must submit to our dictation, and put as few restraints as possible upon those we operate upon, the more especially as experience is beginning to show that these restraints count for nothing in the final good results to be secured.

DISINFECTION OF SPUTA.—There have been placed at the Lariboisière Hospital, an apparatus for the disinfection, by a new procedure of antiseptics, of spittoons used by tuberculous patients. It is to be applied to all the hospitals of the Seine.

TUBERCULAR LARYNGITIS.

Read in the Section on Laryngology at the Thirty-ninth Annual Meeting of the American Medical Association, May 9, 1888.

D. EMMETT WELSH, M.D.,

OF GRAND RAPIDS, MICH.

In point of frequency tubercular disease of the larynx ranks third among the organs so affected; namely—the lungs, intestines, and the larynx. The disputed question as to its primary involvement, or its being secondary to an already existing lung difficulty, has been practically settled; as recently investigated and recorded cases have shown almost conclusively that a primary involvement can take place. Into this dispute this paper will not enter, but will endeavor to show forms of catarrhal inflammation existing primarily as such, as important factors in its production.

There are certain forms of catarrhal inflammation as seen in this vicinity—Western Michigan—attended with an excessive secretion of mucus and, at times, muco-pus. The nose is almost constantly filled with this secretion and the naso-pharynx and pharynx constantly bathed with the same. This secretion is, with difficulty, removed; and the mucous membrane of the nose is at times very noticeably inflamed with points of erosions and tendencies to epistaxis. The pharynx presents this same appearance but with this addition, that it presents a relaxed or flabby condition. The larynx is also flabby, and instead of the pinkish tinge of color it presents a grayish hue. The serous and mucous glands in this condition constantly freeing themselves of their secretion; the mucus passing down the pharynx and lodging in the arytenoid commissure, develops an irritation and provokes coughing. This is further increased by hawking and an extension of the inflammatory action.

The subjects of this condition are generally persons of a strumous habit, or those suffering from repeated attacks of colds, coupled with an already existing impairment of health.

A current of inspired air passing over this kind of tissue, though elevated in temperature and changed from a condition of dryness to one of moisture, is as injurious to the general health as dust and cold laden air is to the finer bronchi.

The stomach is impaired by the commingling of the food and mucus, thus adding another source of injury to an already existing condition. The impairment of health is noticed by loss of appetite, emaciation, pallor, and slightly elevated temperature. You are generally consulted on account of an irritative cough devoid of free expectoration, when, on inspection and examination the above condition is noted, or there occurs later a partial anæmic condition of the palatine arches and the pharynx, and a grayish hue to the larynx, with infiltration of the sub-mucous tissue.

From repeated attacks of inflammatory action the mucous membrane becomes lowered in its

vitality; there is partial arrest of its function, as shown by the loss of endosmotic action of the Schneiderian mucous membrane, due to a lack of absorption of the water which is condensed on its surface and drips from the nostrils. Hence catarrhal inflammations readily follow in those of lowered vitality. Further, there is a loss of elasticity in the capillaries of the part, as seen by the stagnation and retention of blood in them producing congestion of the parts. This stagnation may be complete or isolated, and, serum now being poured out, swellings necessarily result.

Allowing a still higher impaired vitality the serum and mucus exuded will contain pus corpuscles. Pus is not irritating in character, yet under certain circumstances it is rendered ichorous and then it is poisonous and destructive to neighboring tissue. The poisonous part is capable of uniting with and destroying animal tissue, and when absorbed into the circulation destroys the vitality of its constituents, giving rise to abscess and sepsis. Its effects on mucous surfaces are ulceration, mortification, or some actual loss of tissue.

Bearing in mind how easily ulceration of mucous surfaces takes place, we cannot but be surprised at those cases which seeming of minor importance certainly involve solutions of continuity in situations very open to absorption. This ulcerative process taking place in those already debilitated, or particularly those of a strumous habit, renders an abnormal sensibility of certain tissues liable to injury, and is most marked in mucous membranes, and their inflammatory action is exceedingly protracted. When inflammatory action, occurring in healthy individuals, does not lead to or cause death of the part, its product is absorbed or leads to suppuration or the formation of vascular connective tissue. But in struma and those generally debilitated, absorption is retarded and its tendency is to infiltrate and accumulate in the tissue and so lead to caseous change.

Tubercle, in its simplest sense, refers to a most typical stage of a certain tissue change; and to the process which precedes its appearance, as well as that which follows, may the term tubercular be applied. Tubercle is found in the floor of scrofulous ulcers and in certain affections of the mucous membrane, but it is not met with in all. Yet it must be borne in mind that there are grades and degrees of the tubercular process, as well as there are in inflammation.

The tubercular formative action may proceed thus far and, like inflammatory action, not always form pus.

Reindfleisch considers scrofula the starting-point of the tubercle-producing process, and considers that the tubercle is usually derived by a process of infection from some near or distant seat of scrofulous disease, thus tracing the connection between certain eruptions of tubercle in the lung

and a preliminary scrofulous bronchitis. If tubercle appears in a gland, then it is due to a scrofulous catarrh of the mucous surface; or, taking another example, a tubercular ulcer may begin as a catarrh and, after a time, tubercles appear at its base. Scrofula is the soil, tubercle the seed, and their relation confirms the theory that it is especially upon the soil of scrofula that the infection can and does take root and develop. Bearing now in mind the condition above given of the tubercular and pretubercular stage, and the lowered and impaired vitality of the naso-pharynx, and the existing debility of the patient, the proneness with which the mucous membrane becomes inflamed and the secretions of this membrane to become ichorous, and remotely, the formation of pus, I cannot but infer that catarrhal inflammations of the upper respiratory tract enters and creates a formative factor in the production of laryngeal tuberculosis, or even the naso-pharynx. And, knowing that tuberculosis is a disease manifesting itself primarily in the respiratory region, and that many catarrhal inflammations of the lungs begin in the larynx, it is fair to infer that in those cases where the eye reveals what the ear fails to detect, that the larynx is primarily attacked. Pathologically considered, four stages exist: anæmia, tumefaction, ulceration, caries and necrosis. On inspection, the appearances of the above are remarkably noticeable, and certain appearances are almost pathognomonic. Voice failure is a very early symptom, and during conversation a change in the character of the voice is very noticeable. In the beginning is noted a gruff hoarseness, which soon changes to a high falsetto, and gradually passes to a toneless whisper. At times there is complete aphonia.

Impaired respiration in the earlier stages is not a noticeable feature, yet, during the latter stages, dyspnoea may ensue, the result of tumefaction and the mechanical loss of mobility and ulceration of the cords.

Difficulty in swallowing is not always present, but when so, it is undoubtedly the symptom which hastens the death of the patient. At first liquids are only refused, and when taken they pass backward into the naso-pharynx or, from the impediment afforded to the movement of the epiglottis, may pass into the larynx and cause suffocation. As soon as ulceration takes place the pain on deglutition is extreme; thus the patient's refusal of food and the unfavorable termination that soon follows.

Pain on speaking is prominent, and when severe is usually referred to the ear. Cough is a prominent and a very distressing symptom, and in the advanced stages the paroxysms are productive of severe pain and are followed by extreme prostration. At first the cough is an irritative one, as though there was some foreign substance in the throat. Expectoration is only glairy in

character until ulceration is established, when it is mucus and muco-pus.

Hæmorrhage from the larynx is rare, and when suspected it is with much hesitancy we say it originated from the larynx.

During the stage of tumefaction a prominent feature is noticed. There is a pyriform thickening of the membrane covering the arytenoid cartilages and the commissure. This thickening is characteristic. The shape of the cartilages is completely masked by this club-shaped swelling, and it may extend upward to near or above the level of the cartilages and fill up the space between them. Previous to ulceration there are small whitish-gray patches noticeable either on the arytenoids or ventricular bands, existing singly or in groups. They are of short duration and ulceration speedily follows. Ulceration developing their peculiar character is a worm-eaten appearance, showing that degeneration has commenced in the deeper tissues. The ulcers are small and isolated at first, but soon unite by breaking down the intervening tissue and forming large ulcerative surfaces.

The following cases presented themselves for examination:

E. W., æt. 21 years, occupation mechanic. Had suffered from nasal catarrh for several years and complained of a dry, hacking cough and frequent attacks of nasal hæmorrhage. The nostrils and naso-pharynx were constantly filled with a mucus when, on its removal, the mucous membrane of the nares was inflamed, and the naso-pharynx and the larynx were of a lustreless color and presented a relaxed and flabby appearance. On phonation the distinctive features of the cartilages of Wrisberg and Santorini were masked and the vocal cords inflamed. The voice was changed in character to a marked gruffness. There was impaired appetite, emaciation, slight elevation of temperature, and a constant irritative cough. On auscultation and percussion the lung revealed no difficulty, yet there was a strong history of scrofula.

The nares and throat were sprayed with an alkaline spray, using Dobell's solution every day, and following the same up by spraying the throat with zinci. sulph., gr. ij to aq. 3j, on alternate days insufflation to the larynx of a finely triturated powder containing iodoform, tannin and bismuth sub. nit. Internally, syr. ferri iodid., syr. hypophosphites, Fellows; and free outdoor exercise. A continuance of this treatment was carried out for three months, when the patient increased in weight, the cough and hæmorrhage had ceased, and I discharged the case as well.

My second case was similar to the first, with this addition, that on the arytenoids and ventricular bands there were isolated points of ulceration, and more marked constitutional trouble and partial aphonia.

The changes made in treatment were the omission of tannin by insufflation, using iodoform and bismuth in equal proportions. After four months' treatment this case improved and, seemingly, is well now, and six months have elapsed.

It is unnecessary to enter into details of the different forms of treatment, as each case presents its peculiar characteristics. I think many cases will improve, and particularly of those persons under 21 years of age. When local treatment has been very noticeably beneficial to the laryngeal difficulty, and there exist deposits in the lungs, a change of climate is need. Colorado or New Mexico are preferable. In the stage of ulceration little or nothing can be done, save to alleviate the distressing symptoms as they arise. Care should be taken not to fatigue the patient by local treatment, allaying the pains and difficulty of deglutition by first cleansing the parts with some alkaline solution and then spraying the throat with a solution of cocaine; after which applying morphia, iodoform, and acacia or bismuth, and endeavoring to render the patient's last hours as comfortable as possible.

BINOCULAR ASTIGMATISM.

Read in the Section on Ophthalmology at the Thirty-ninth Annual Meeting of the American Medical Association, at Cincinnati, May 7, 1888.

BY H. CULBERTSON, M.D.,

OF ZANESVILLE, OHIO.
ASSISTANT SURGEON U. S. ARMY (RETIRED).

I have not infrequently encountered cases of astigmatism in which, after having corrected the error in each eye separately, and on testing both eyes simultaneously, in binocular vision, have found that vision proximum was not perfect, and in order to attain normal vision near at hand, in binocular sight, the angle denoting the axis of the cylindrical glass must be changed in one or both eyes.

In correcting this binocular defect, types and the astigmatic bars were employed. If the patient looks upon the floor it will seem to incline to the right or left, and on changing the axis of one or both cylinders, the surface will appear level. But the same defect will be apparent if a board 12 x 3 inches, with parallel sides, be held in front of the patient at one metre, and on a level with the eyes.

In these cases then, the answer will be, that the right or left end of said "object-board" is wider than the other. The angle of one or both cylinders is changed until each end of the "object-board" seems equally wide, or in other words, the sides are parallel; and then it will be found that the astigmatic bars are seen normally in near or far vision, in binocular vision. All of my refraction cases are estimated, not only by the usual methods, but the test as given is applied to all cases of astigmatism before the investigation is regarded as complete.

The use of glasses thus adapted has been successful in practice, with one or two exceptions, and in these the use of cylinders had to be dispensed with and spherical glasses employed.

This defect in binocular vision does not occur, of course, in all cases of astigmatism; but observation has taught me that such errors are far from being uncommon.

The following explanation offered of binocular astigmatism, seems more rational than any other with which I am familiar:

If a perpendicular be raised anteriorly and horizontally midway between the eyes from a base line intersecting each *fovea centralis*; then, in testing each astigmatic eye separately, the *axis of vision* will, in *vision remotum*, be parallel to said perpendicular. If the ocular muscles are normally balanced in action, the plane which cuts the visual axis in the cornea will be vertical. In the normal eye, *its fellow being covered*, during vision proximum, *still* the visual axis may be parallel to our perpendicular, and hence the angle of the axis of the cylindrical glass may often be the same in remote and near vision, *when each eye is tested singly*. In binocular vision, when astigmatism is present, the distance is so great, in remote vision, that the visual axes are each parallel to our perpendicular and to each other, and when the ocular muscles are harmonious in action, types and astigmatic bars are seen in normal form. So will vision be perfect near at hand, in astigmatism, provided this due balance is maintained in these muscles; but it is evident that, in proximal vision, the interni inferior oblique and superior and inferior recti muscles must exercise increased force and act in concert.

If these muscles do this, there can be no binocular astigmatism (in the sense cited) which requires re-correction, after each eye has been separately corrected, and *in vision near at hand*. But if these muscles are not harmonious, then the plane of the rays of light remaining the same, that is, vertical, and the *axis of rotation* of the eye at its upper extremity, inclining to the right or left, then it follows that the relation of the axis of the cylinder and the astigmatic meridian of the cornea has been changed, and in order to restore this relation the axis of the cylinder must be made to correspond with the modified position of the defective corneal meridian.

Let the following case illustrate: In binocular and proximal vision, suppose the left inferior oblique fails to act sufficiently to maintain the axis of rotation vertical, and that the inner fibres of the left superior rectus inclines said axis, at its upper extremity, towards the nose; then the rays of light will no longer cut the cornea in its vertical meridian, but towards the temporal side of—the should-be—vertical plane of the cornea. If the defective axis of the cylinder was at an angle of 180° in vision remotum, for proximal vision

the axis of the glass will have to be turned upward towards the displaced axis of rotation of the eyeball, as many degrees as *this* axis has deviated from the normal vertical perpendicular. If to 10° , then the angle would be 10° instead of 180° for the cylinder, the scale running from the temporal side. In other words, the measure of the deviation of the axis of rotation is the number of degrees of axis-displacement of the cylinder required in order to cause both sides of our "object-board" to appear parallel.

By trial the proper degree is found and in which eye the correction should be made, or if both eyes should be corrected.

In remote vision, the ocular muscles may or may not be harmonious, but if these are normally balanced in action when accommodation is at rest, it is not difficult to comprehend when the muscles supplied by the filaments of the third nerve are active, as in vision proximum, that this relation may be modified, and the *axis of rotation* so changed as to demand a re-correction for near and binocular vision. This change of cylinders does not interfere with normal vision remotum.

As these changes in the axis of the cylinders are observed in remote vision when the eyes are under the full influence of mydriatics, it results that the modification in the axis of rotation cannot be due, at least directly, to accommodation. This may be illustrated by the following case:

Miss S. L., aged 28 years. When under duobiose, she requires in the R. E. — 1.0 sp. \odot — 0.5 ax. 130° , and in L. E. — 0.75 \odot — 0.5 ax. 40° , V. 2, = $\frac{1}{4}$, and the astigmatic bars appear normal. But in binocular vision, when the "object-board" is placed at one metre, the left end of said board seems wider; when the left cylinder is turned to 30° the sides of "object-board" are seen parallel, and the floor is level. When the effects of mydriatic had passed off, a week later, the cylinders at 30° and 130° induced seeming parallelism of the "object-board" and a level floor.

A few cases will be given illustrating the change of axis of cylindrical glasses in order to obtain normal and proximal binocular vision.

Case 1.—Miss A. V. C., aged 18 years. Under duobiose she requires in R. E., — 0.5 ax. 90° , V. = $\frac{1}{4}$; and in L. E., — 1.25 ax. 45° , V. = $\frac{1}{4}$. At one metre the "object-board" is narrower at the left end and floor inclines to her left in binocular vision. On turning the left cylinder to 60° the floor appears level and the sides of the board parallel; and the distance types and astigmatic bars are now seen normal.

Case 2.—Miss M. C., aged 27 years. Without mydriatic her case reveals that she requires in R. E., + 4.5 \odot + 1.25 ax. 105° , V. = $\frac{2}{3}$ and $\frac{2}{3}$ D.; and in L. E., + 2.5 \odot + 1.5 ax. 120° , V. = $\frac{2}{3}$, and $\frac{1}{2}$ D. V. 2, = $\frac{1}{2}$, and $\frac{1}{2}$ D. The "object-board" sides are not parallel in binocular vision at one metre or the floor level, until the left cylin-

der-axis stands at 120° , which later does not correspond with the axis of the right eye, or 75° .

Case 3.—Miss A. H. B., aged 31. Without mydriatic, requires in R. E. $+0.5 \text{ C} + 25 \text{ ax. } 60^\circ$, V. $= \frac{1}{4}$ and $\frac{3}{30} \text{ D.}$; and in L. E. $+0.5 \text{ C} + 0.25 \text{ ax. } 100^\circ$ V. $= \frac{1}{4}$ and $\frac{3}{30} \text{ D.}$ But binocular vision at one metre is not normal unless the axis of right cylinder is at 60° , in lieu of 80° , which latter would correspond with the axis of 100° in the left eye.

Case 4.—Miss J. R., aged 31. Under duboisine, she required in R. E. $+0.75 \text{ ax. } 50^\circ$, V. $= \frac{1}{4}$; and in L. E. $+0.75 \text{ ax. } 140^\circ$, V. $= \frac{1}{4}$. But binocular vision at one metre is not normal when the axis is at 130° left eye. A week later, when the effects of the mydriatic had passed off, binocular vision was perfect with the angles 140° and 50° in far and near vision.

Case 5.—Mr. J. G. S., aged 18 years. Under duboisine he requires in R. E. $+0.75 \text{ ax. } 40^\circ$, V. $= \frac{1}{4}$, and in L. E. $+0.75 \text{ ax. } 90^\circ$, V. $= \frac{1}{4} = \text{V. } 2$. After the effects of the mydriatic had passed off the axis of the right cylinder had to be turned to 90° in order to obviate binocular astigmatism at one metre, and then vision remotum was perfect.

Case 6.—Mr. J. N. S., aged 34 years, requires $+2.75 \text{ ax. } 75^\circ$, V. R. E. $= \frac{1}{4}$, and with $+3.5 \text{ ax. } 90^\circ$ V. L. E. $= \frac{1}{4}$; V. $2 = \frac{1}{4}$, and $\frac{3}{30} \text{ D.}$ But the "object-board" was not seen parallel at one metre. On turning the left cylinder axis to 105° , binocular vision, near and far, became normal so far as glasses could accomplish, and these continued to serve him well.

Case 7.—Mr. F. G., aged 27 years, under duboisine requires R. E. $+1.25 \text{ ax. } 180^\circ$, V. $= \frac{1}{4}$, and in L. E. $+0.5 \text{ ax. } 180^\circ$, V. $= \frac{1}{4}$. But V. 2 , while $= \frac{1}{4}$, reveals the sides of the "object-board" not parallel. On turning the axis of the right cylinder to 30° the "object-board" is seen normally and V. $2 = \frac{1}{4}$ and $\frac{3}{30} \text{ D.}$

Case 8.—Mr. L. I., aged 19 years, without duboisine the angle for each eye was 90° , but when under this mydriatic he required in R. E. $+3.5 \text{ ax. } 70^\circ$, V. $= \frac{1}{4}$, and the same cylinder in L. E. at 100° V. $= \frac{1}{4}$. The bars and types were seen normally, V. $2 = \frac{1}{4}$ and $\frac{3}{30} \text{ D.}$ These glasses were given and failed to give proper vision. He was given $+3.5 \text{ ax. } 90^\circ$ for each eye, and binocular far and near vision became normal. He was not brought under mydriatic at the second application. It is certain that this patient under the mydriatics saw in binocular vision normally, but after accommodation was fully restored vision was abnormal in each eye with the first glasses, and to secure binocular far and near vision each cylinder was changed to 90° . This result may be due to the stimulus of accommodation exciting through the filaments of the third nerve, the superior recti in each eye. It is true that with the cylinders at 90° in each eye vision remotum of the bars and

types was normal. This can only be accounted for on the supposition that, *even in remote vision*, there must have been present accommodation. It is also true in this case that this ametropia developed $= \text{D. } 4.5$. Astigmatic hyperopia in each eye under duboisine, but accepted only a $+3.5$ cylinder when the effects of the mydriatic had passed off. He, therefore, was exercising $= +\text{D. } 1.0$ of accommodation for distant vision, and it is probable this would stimulate the superior recti sufficiently to change the axis of rotation in binocular remote vision to 90° each eye. This man's unaided near point was 19 cm. $= \text{D. } 5.3$, and as he had $= 4.5 \text{ D.}$ of hyperopia, his accommodation was $= +4.5 + 5.3 = +9.8 \text{ D.}$, which is equal to what he should have had at 20 years of age. In correcting $+3.5$ of this astigmatism he would possess an excess of accommodation $= 9.8 - 3.5 = 6.3 \text{ D.}$ in proximal vision.

Case 9.—Miss M. C., aged 30 years. Without duboisine and with $-1.0 \text{ C} - 0.75 \text{ ax. } 25^\circ$, V. R. E. $= \frac{1}{4}$, and with $-1.25 \text{ C} - 0.75 \text{ ax. } 150^\circ$, V. L. E. $= \frac{1}{4}$, V. $2 = \frac{1}{4}$. In binocular vision at one metre the right cylinder gave only normal vision when the axis was turned to 180° or 0° , or horizontally. Then the floor was also level, the bars alike, and types seen normally in far and near vision. After the effects of the mydriatic had passed off these results held good.

Case 10.—Miss A. B., aged 23 years. Without mydriatic and with $-0.5 \text{ C} + 0.25 \text{ ax. } 180^\circ$, V. R. E. $= \frac{1}{4}$, and with $-1.75 \text{ C} - 1.75 \text{ ax. } 180^\circ$, V. L. E. $= \frac{1}{4}$ and V. $2 = \frac{1}{4}$ and $\frac{3}{30} \text{ D.}$ On using duboisine the formula became $-0.25 \text{ ax. } 145^\circ$, and V. R. E. $= \frac{1}{4}$ and $\frac{3}{30} \text{ D.}$; and $-1.0 \text{ C} - 1.25 \text{ ax. } 180^\circ$, V. L. E. $= \frac{1}{4}$ and $\frac{3}{30} \text{ D.}$, and V. $2 = \frac{1}{4}$ and $\frac{3}{30} \text{ D.}$ Now the "object-board" sides were parallel, the floor level, and the bars normal; but the tests for binocular vision were not normal when the axis of the right cylinder was placed at 180° . These glasses held good subsequently.

It may be claimed that the foregoing results are due to our not having found the correct axis in the monocular tests of each eye. This assumption would be untenable, because every care was taken in correcting each eye singly, both in far and near vision; but on attempting binocular vision, especially at one metre, or less, distance from the ametropia, the sides of the "object-board" were not seen parallel, nor the floor level. When the axis of one or both cylinders were changed, then, and then only, binocular vision-tests became normal. But in these cases the axes of the cylinders did not correspond.

The explanation given may not be the true solution, and accommodation may have a direct influence in the result, by changing the form of individual sectors of the crystalline lens, but the fact remains that there is such a phenomenon as *binocular astigmatism*.

If, in calling your attention to this subject, I

shall induce any to investigate it, and possibly determine the true solution, I shall rest content with the result.

Zanesville, O., May 7, 1888.

THE FORCIBLE AND IMMEDIATE REDUCTION OF OLD SUBLUXATION OF THE TIBIA.

Read in the Section on Surgery, at the Thirty-ninth Annual Meeting of the American Medical Association, May, 1888.

BY E. H. BRADFORD, M.D.,
OF BOSTON, MASS.

The subluxation of the tibia in chronic disease of the knee-joint is so common a deformity that no description of it is needed. It is well understood that it is caused by the reflex spasmodic contraction of the hamstring muscles pulling the tibia backward in a joint whose ligaments and capsule have been relaxed by disease. This relaxation is not often to be demonstrated clinically, as motion of the sort causes pain usually—occasionally, however, cases will be met where the inflammatory process is so subacute that the tibia can be pushed forward and back without pain, owing to the relaxed condition of the posterior capsule and the crucial ligaments. This painless condition is of course not so uncommon in the knee-joint affections occurring in tabes (spinal arthropathies, Charcot's disease).

In cases of severe tubercular osteitis, when a spontaneous recovery has taken place, with fibrous ankylosis and subluxation of the tibia, it will be found in the severest cases that the cicatricial contraction of the capsule is so firm that, on attempting to forcibly straighten the limb, the head of the tibia cannot be made to slide forward as it should, but is held back in its position of subluxation not only by the hamstring tendons, but largely by the posterior wall of the contracted capsule of the joint. If the limb is pulled straight the tibia remains subluxated. In the lighter cases the head of the tibia can be pushed or pulled forwards manually, either with or without the help of tenotomy of the hamstrings, or by means of a mechanical appliance the subluxation can gradually be corrected. In the severest cases, however, this cannot be accomplished—or only accomplished after the prolonged employment of considerable and painful force.

A moment's reflection is sufficient to show that raising the lower part of the tibia, if the latter is subluxated at the knee, will not correct the deformity; neither will a simple pull upon the leg, separating the tibia from the femur, unless there is also a pressure upon the head of the femur forward. This latter is impossible while the posterior ligament is so strong as to resist such forward pressure.

In order to determine the practicability of

stretching the resisting ligaments in a normal knee-joint, experiments were made through the kindness of Prof. Dwight, of the Harvard Medical School, using on a cadaver the appliance to be described, and it was found that the tibia could be pushed forward (*i. e.* subluxated forwards) fully an inch. The first resistance encountered is the posterior crucial ligament, which becomes torn after the application of considerable force. The posterior ligament can be stretched and affords but little resistance in a normal joint.

In the distortion following chronic disease of the knee-joint with flexion at the knee and the head of the tibia subluxated, no resistance to correction will be found from the crucial ligaments which are absorbed in the morbid process, but the posterior ligaments and the posterior wall will, in cases of long standing, be found extremely firm. In such cases, before the limb can be made straight and the subluxation corrected, the contracted posterior ligaments and capsule must be stretched, enabling the tibia to slide over the condyles of the femur as in normal extension at the knee-joint. This can be accomplished in the following way: The patient being under the influence of an anæsthetic, the knee should be forcibly flexed in order to break up the intra-articular adhesion. The apparatus indicated in the accompanying diagram is then applied to the limb and pressure

from behind forwards, by means of the screw force, brought to bear upon the head of the tibia, counter-pressure being exerted on the ends of the condyles and the lower end of the tibia. The vessels and nerves lying deep in the popliteal space being well protected by the bellies of thick muscles, are in no danger of injury by such pressure, and the skin, as has been abundantly proved by osteocla-

sis, is capable of bearing without injury a great amount of momentary pressure. When the head of the tibia has been pushed forward to an extent the limb may be extended, and if it is found that some subluxation still remains, the procedure should be repeated or continued until entire correction is accomplished. After this is effected the limb should be held straight and secured against recontraction by a plaster of Paris bandage applied high up in the thigh and including the whole leg and foot. The patella and joint should be well protected by cotton before the application of the bandage. Or, instead of a gypsum bandage, an appliance of the principle of a Thomas knee splint may be used.

There is considerable pain for a day following the operation, but beyond that but little inconvenience; the patient should be able to go about using crutches in a few weeks. The plaster bandage should be worn a month or so, and for some time subsequent some form of retention appliance to prevent recontraction.

The procedure is only indicated in a limited class of resistant cases, and is manifestly contraindicated in acute cases. The writer has found it of service in the two following cases:

Case 1.—M. H., æt. 22. Caries of the knee-joint at the age of 4. Has never been able to walk since that time without the use of crutches or cane. Complete recovery took place, except that a marked amount of deformity was left. The patient was unable to place the heel to the ground and could bear but little weight upon the toe, the leg being flexed at an angle of 130° with the femur. Marked subluxation of the femur was present. The joint was perfectly stiff.

Forcible correction was applied in the way described, and the limb fixed with a plaster bandage for two months. Crutches were discontinued at the end of six months, and at the present time the patient can stand upon the whole foot; the subluxation has been entirely corrected. Flexion of but a few degrees exists (10°), and the patient is able to walk without a cane, though using one by preference.

Case 2 resembles Case 1, except that the patient is a boy of 12 and the deformity has persisted not more than four years. Correction was made as in Case 1, and with a satisfactory result.

DR. PANCOAST, of Philadelphia, thought the method proposed by the essayist an admirable one for replacement of the tibia in the form of displacement under consideration; for, unless we adopt this or some other means of pressing the tibia to the front and retaining it in that position, our efforts will be a failure. We do not have the posterior ligament much interfered with; but the great danger is not only to the blood-vessels, but also to the nerves. I know of cases where the nerves have been injured; where the hamstring

tendons have been ruptured; where the arteries have been injured, and where gangrene supervened. Now, if we think that by forcing the foot forward we stretch the posterior ligament, we make a great mistake. That ligament is going to resist stretching as long as possible. Ligaments are made, not for stretching, but for the purpose of allowing motion of the joint without yielding. If you pull upon a man's arm with as much force as you can summon you will see that there is no stretching of the ligaments. They are made for inelasticity. If there is yielding of ligaments, it is because the ligaments are in a pathological condition. It must be after they have been pathological for a long time. In cases of "white swelling," synovitis of the knee-joint, the white fibrous tissue undergoes a change; it does not undergo a sudden change and it does not stretch, but during the time that it is undergoing the process of which I have spoken, it is absorbing moisture, and thus enlarges slowly, by capillary enlargement. Every one of us knows that it is a very slow process. So it is in cases of any joint. I have a case now under my care in which I am at a loss to know whether to use *brisement* force or not, or whether it would be better to reduce it by gradual pressure. It is difficult to say, too, whether cutting down upon the joint and removing a V-shaped piece of bone, and then restoring the position of the limb, is not the best procedure in most of these cases.

DR. D. McLEAN, CHAIRMAN: I am glad that Dr. Pancoast did not allow this interesting paper to go by default. We recognize certain of these cases of subluxation which we can rectify; but to think that we can do so in old cases of long standing is, I think, too much. In those cases the structures about the joint undergo too much change, and I do not think that it is safe or rational to think that we can do much in these cases. It will take the reports of more than two cases to lead us to endorse the procedure under consideration. I am inclined to adopt what Dr. Pancoast says with reference to exsection, that it is questionable if it is not the best procedure in many of these cases.

EXOPHTHALMIC GOITRE AND ITS TREATMENT BY TINCTURE OF STROPHANTHUS.

*Read before the Mississippi Valley Medical Society, at St. Louis, Mo.,
September 25, 1888.*

BY DANIEL R. BROWER, M.D.,

PROFESSOR OF DISEASES OF THE NERVOUS SYSTEM IN THE WOMAN'S
MEDICAL COLLEGE; LECTURER ON THE PRACTICE OF MEDICINE
IN RUSH MEDICAL COLLEGE, SPRING COURSE,
CHICAGO, ILL.

In this paper I desire to invite your attention anew to the more prominent features in the clinical history and diagnosis of exophthalmic goitre, and suggest its treatment by strophanthus.

The eyes, the thyroid gland, and the circulatory system are usually all perverted by the morbid process in this disease. The order of their sequence varies, but usually the circulatory disorders are first manifested. These consist of increased frequency of the pulse, palpitation, and dilatation of the arteries. The pulse in a mild case is about 100, but it may reach such a point in frequency as is impossible to count. The frequency varies with the emotional condition. Indeed, the impression made by the heart's action is one of intense nervous excitement in the cases generally. In the early stages the heart sounds are normal, but anæmic murmurs may soon be found, and later along, organic murmurs—organic murmurs that have resulted from the dilatation of the heart. This dilatation is a condition invariably present in chronic cases. The arteries are dilated and show increased pulsation, due in part to the increased force of the heart's action, but more especially to the lowered tonus of the vessels. Pulsation is especially manifest in the carotids, thyroid arteries, and the abdominal aorta. The goitre, ordinarily, does not show itself until some time after the cardiac symptoms. It is a soft, elastic, and painless enlargement, usually symmetrical, but often the right side is more enlarged than the left. The enlargement is seldom great, and it undergoes frequent changes in size from emotional disturbances, and may be absent altogether. There can usually be detected a loud blowing murmur, and sometimes distinct pulsation in the gland itself. They are very rarely present in the ordinary bronchiocele, hence are of value in differential diagnosis.

The exophthalmos usually appears soon after the swelling of the thyroid, but occasionally before it, and still more rarely may precede it and the cardiac symptoms. In some cases it is absent altogether. The degree of exophthalmos varies from a slight prominence to such an excessive protrusion that no part of the globe is covered by lids. It is usually bilateral, but not always symmetrical; it often appears earlier in one eye than in the other, and the prominence of the one may exceed that of the other.

The ophthalmoscope will show pulsation in the arteries of the retina, when this pulsation can scarcely be detected elsewhere; hence this method of examination is a valuable aid to diagnosis.

Von Graefe first called attention to another useful diagnostic sign about the eyes, and that is a want of harmony between the movements of the eyeball and the upper lid. If you direct the patient to cast the eye downwards it will be found that the upper lid does not follow the movement of the eye at all, or if it does, then abnormally.

The temperature of the body is usually elevated from .5° to 1° Fahr. A muscular tremor, sometimes coarse and jerky like chorea, and sometimes fine and regular like paralysis-agitans, is

present in almost every case. It is confined in great part to the larger muscles. The head, fingers, and toes are usually exempt from this tremor. All the organs of the body sympathize more or less with the ordinary complexus of symptoms.

The gastro-intestinal area often shows loss of appetite, impaired digestion, nausea, vomiting and diarrhoea, and as a result there is marked emaciation.

The nutrition of the brain suffers much and is manifest in insomnia, headache, dizziness, weakness of thought and memory, irritability of temper, neuralgia; and this disordered nutrition not rarely leads up to insanity.

The respiratory system shows disorder in cough, oppression in breathing, and intercostal neuralgia.

The diagnosis of exophthalmic goitre, when the three classical symptoms are present, is easy, but in cases where the exophthalmos is absent, and where both goitre and exophthalmos are scarcely perceptible, there will be found great difficulty. In these cases the ophthalmoscope, as above mentioned, is a valuable aid; and the milliampère metre will also give valuable information, as first suggested by Dr. Vigorius, by determining the condition of the electrical resistance, which in this disease is markedly diminished.

The morbid anatomy and pathology is no nearer solution than it was in 1825, when Páry first described its symptoms. The various theories that have been proposed have been summarized in an excellent article by Dr. A. A. Eshner.¹ He reaches a conclusion that seems to be the most reasonable: That the symptoms are due to a disorder, functional in character, in the medulla oblongata, involving the cardio-inhibitory centre, the vaso-motor centre, the respiratory centre, and the other important centres located in that part. A careful consideration of the physiological functions of these centres will enable us to work out without much difficulty the pathogenesis of the disease.

The prognosis should be guarded. The disease may not only terminate fatally, according to von Graefe, in about 12 per centum of the cases, but not infrequently terminates in insanity. A great majority of the cases will certainly, if recognized early, yield to treatment. Early diagnosis is exceedingly important, for when structural changes have taken place in the heart and thyroid, the prognosis is unfavorable.

The treatment of this disease has been very unsatisfactory. The drugs in ordinary use have but little influence upon it; but I think we have found in *strophanthus* a remedy that in some cases is certainly of great value. I have administered the tincture of *strophanthus* in three cases with benefit. In the first case, a man 21 years old, who had been under the ordinary treatment

¹ "The Polyclinic," Philadelphia, July, 1888.

—tonics, alteratives, rest, electricity, for three months without any abatement of symptoms—indeed, with a steady progression of the disease, I commenced the use of tincture of strophanthus, 2-drop doses every six hours. The pulse at this time was so rapid that I could not count it. The dose was gradually increased, and when 10 drops were given the circulation was under control; pulse, when quiet, was 85 per minute. The exophthalmos and goitre gradually disappeared, and in about four weeks he was well. The strophanthus was gradually withdrawn and tonics substituted. This result was reached about eighteen months ago, and the patient continues well.

The second case was a female, aged 52, in whom the disease had continued about eighteen months. The strophanthus was given to her in about the same manner and about the same dose was necessary. An equally good result was obtained.

The third case has been under observation about ten days only, but the same influence is manifest as in the other two cases.

Dr. Norman Bridge, of Chicago, has administered the drug in two cases at my suggestion. In one case no effect was observed; in the other case he combined tonics with the strophanthus, and the patient made a rapid recovery.

Dr. E. Fletcher Ingals, of Chicago, tells me that he has administered it in one case, pushing the dose to ten minims, three times a day, with benefit. In his case, he was using at the time he began the strophanthus hypodermic injections of carbolic acid, but he attributes the improvement in the case principally to the strophanthus.

I do not advise reliance solely upon strophanthus, but ordinary hygienic rules must be observed, such as the avoidance of fatigue, physical and mental excesses, a careful, regulated diet, attention to bowels and skin. I also advise the use of ordinary tonics, and the application of galvanic electricity to the cervical sympathetic nerves.

I also desire to call the Society's attention to the seeming value of strophanthus in other diseases that sometimes, at least, have their origin in disordered nutrition of the medulla, such as epilepsy, megrim, and, through its influence upon the medulla, as an agent in controlling maniacal excitement, such as acute delirious mania. I feel confident that it will materially assist in relieving the febrile state, as well as in protecting the heart against the depressing influences of the ordinary remedies used for this purpose.

THE BILLINGS MURDER TRIAL. A MEDICO-LEGAL QUESTION.

BY D. M. WICK, M.D.,
OF NEW HARTFORD, IOWA.

On the evening of the 21st of last December W. S. Kingsley, a young lawyer of Waverly,

Iowa, was found dying on the floor of his office with a bullet hole in his head. His left hand clinched tightly certain papers, while his right hand lay open, a few inches from right thigh, and a revolver, with two empty chambers, was found under right leg. A post-mortem examination was made. The ball (32) entered the skull at a point between the root of right nasal bone and eyebrow, passing to the right of the *cristi galli*, through right brain, circle of Willis, rupturing vessels, and lodged a half inch within left brain. Length of wound, five to six inches. The ventricles and cavities were filled with clotted blood.

Death occurred within ten minutes. M. E. Billings was arraigned as the murderer.

The State attempted to prove that a bullet wound in the brain, causing instantaneous rigor mortis of the left hand, would also cause the same condition in the right hand, providing the revolver was held in this hand at the time the ball was fired. In support of this, the doctors making the post-mortem were put upon the stand. Counsel, in pleas, also read from Wharton & Stillé's Medical Jurisprudence, Sec. 722, Vol. 2, 4th edition. The defense read numerous citations from various medical works, to show that the brain has certain motor tracts controlling the actions of certain muscles; that by vivisection, a portion of the brain of a living animal may be removed and certain results follow; this wing, or that leg, or that set of muscles are affected.

Medico-legally, the above is a nice question to decide. Evidently, both the State and defense attempted to solve this problem by considering rigor mortis produced through the agency of the nervous system, either from injury to the nerve centres or from blood-clots in the ventricles.

Tidy quotes Beclard and Hermann, stating rigor mortis is altogether independent of the nervous system, and further states that the nerve supplying the muscle, or indeed the removal of the entire brain and spinal cord during or before its occurrence, in no way affects it. Because the dying man was found with the left hand firmly grasping papers, while the right hand was open and near the revolver, is there any evidence, in a medico-legal view, that he fired the fatal shot himself and then let go the weapon? or was it placed under the right leg by his murderer?

OVERWORK ON RAILWAYS.—It is stated that the Board of Trade of England have ordered the principal railway companies to supply them with returns showing every occasion during two typical months this year and last on which any man concerned with the working of the traffic was on duty for more than twelve hours continuously. It is believed that the Government contemplate the introduction of a measure dealing with the subject.

MEDICAL PROGRESS.

ANEURISMS AND TUBERCLE-BACILLUS.—In a paper read before the Académie de Médecine, M. GERMAIN SÉE said that he had been struck by the fact, especially since the discovery of the tubercle-bacillus, that patients suffering from aneurism of the aorta often become tubercular, and die of pulmonary phthisis, attended with the formation of cavities, and progressing slowly without fever. This was observed by Stokes, and numerous cases can be found in the records of Pathological Societies. Out of 24 cases of aneurism under his own care, 7 were thus affected with pulmonary tuberculosis. It is now well-known that patients with cardiac affections are not exempt from phthisis. C. Paul has shown the frequent occurrence of phthisis in cases of narrowing of the pulmonary artery. Aortic aneurism must now be considered one of the agents favoring the development of the tubercle-bacillus. In aneurism, from the disturbance of the circulation there is a stagnation of the venous blood, and diminished activity of the gaseous exchanges between the gases of the blood and those of the atmosphere. In this internal gaseous medium (in the alveoli of the lungs and smallest air-passages) the bacillus appears to multiply when it enters the body by the respiratory tract. In aneurism the air is imperfectly renewed in the whole of the lungs, just as in normal conditions it is imperfectly renewed in the apices as compared with the rest of the lungs. In short, excess of oxygen hinders, deficiency favors the development of the bacillus. In this way the multiplication of the bacillus is accounted for; the way in which it penetrates into the pulmonary parenchyma in patients of all ages who are affected with aortic aneurism, remains to be shown.

Lately it has been found that ulcerative endocarditis, or even simple endocarditis, with vegetations is caused by a staphylo-coccus; rarely by a strepto-coccus; more rarely still by the tubercle-bacillus. The analogies between endocarditis and endarteritis allow us to suppose the existence of an endarteritis, due to the presence of a microbe. Are the lesions that affect the internal and middle coats of an artery which has undergone aneurismal dilatation caused by a bacillus? If this question is answered in the affirmative, one can easily explain how the bacillus is washed away from its position in the aneurismal wall to the lung and there multiplies.

In the treatment of aneurism M. Sée relies on iodide of potassium, the mode of action of which he explains as follows:

1. It relieves the dyspnoea due to catarrhal affections of the bronchial tubes by liquefying the effused secretions.

2. It aids the intra-pulmonary circulation, and diminishes venous stagnation.

3. The volume of the aneurismal tumor is diminished by contraction of the adventitious coat and the tissues surrounding it.

4. By reducing the size of the tumor, the pressure on the adjacent nerves is relieved, and pain therefore mitigated.

He gives the iodide in the amount of 30 grains daily, divided into three doses, to be taken at the beginning of a meal.

For the relief of pain he has found subcutaneous injections of antipyrin most efficient. When a cardio-vascular tonic is required he has obtained good results from sulphate of sparteine, and rejects altogether caffeine and digitalis.—*Bulletin de l'Académie de Médecine*, Aug. 14, 1888.

GLYCERINE AS A SURGICAL DRESSING.—MR. CHARLES E. S. FLEMMING says: We want a dressing that is non-irritating, antiseptic, will not become adherent, will allow free drainage, will not allow the discharges to get hard and caked, will be freely miscible with the discharges, and not evaporate at any temperature of the body nor occupy the place intended for the discharges. We have, I think, what we want in the glycerine of starch of the Pharmacopœia, with some antiseptic dissolved in it; for example, corrosive sublimate 1 in 1,000 parts. The starch, added for convenience of applying the glycerine, in addition forms a non-irritating surface to apply to the wound and is a mechanical protection; it is most conveniently applied thickly spread on one or more layers of Gamgee tissue or some absorbent wool. This application is not irritating, is antiseptic, and is removed with the greatest ease from any wounded surface. As glycerine is freely miscible with the discharges it is quite absorbent, discharge in passing into and through the dressing becomes mixed with the glycerine, and as this does not evaporate it is thus prevented from becoming caked or hard and dry. The glycerine, itself hygroscopic, does not usurp the place of the discharge nor prevent the free escape of the watery vapors. Such a dressing after several days will be found moist, soft, flexible, and easily removed; it is heavy with the quantity of fluid it contains, a proof of its absorptive powers. The discharges are not collected in one spot. Next the wound there is a jelly-like layer which is easily removed, leaving a clean surface, and the sutures, if any, distinct and easily taken out, not being caked with blood.

In my own practice I have found healing of incised wounds under this dressing quick and accurate, and the dressing of lacerated and contused wounds is absolutely painless and very quick; I have found it of much benefit in those chronic granulating wounds which every dressing seems to irritate, and have applied it with success as a

daily dressing in two cases of purulent conjunctivitis. I have not had an opportunity of trying, but should think glycerine and starch might be used with advantage in skin grafting.—*British Medical Journal*, Sept. 22, 1888.

CONNECTION BETWEEN ALBUMINURIA AND DISEASE OF THE PLACENTA (*Schmidt's Jahrb. d. Mediz.*)—Fehling has recently drawn attention to to connection between nephritis and disease of the placenta, relative to death of the fœtus, and further investigations since then have confirmed his (Fehling's) views. WIEDOW refers to a series of old published cases which, without having been properly explained then, speak for the relation of both diseases; Simpson, of Edinburgh, regarded already early in the year 1860 albuminuria as the cause of disease of the placenta. Lately cases of this kind have also been described by Cohn, to which are added in Wiedow's treatise further observations from the "Freiburg Clinic." Mostly eclampsia intra or post partum, morbid kidney of pregnancy, were in question; once the necropsy revealed contracted kidneys; dead or extremely insufficiently nourished children and with it regularly anatomical changes of the placenta were found. Microscopically these appeared as numerous yellowish-white nodes, belonging either to the maternal portion of the placenta, or being found on the surface. Microscopically, according to Wiedow's researches, they represented the result of a coagulation and necrosis of the follicular epithelium. That there exists a connection between albuminuria and disease of the placenta is scarcely to be doubted; but difficult to answer is the question whether the change in the placenta is the consequence or cause of the albuminuria. For some cases the former view will hold good, but not for all. Sometimes normal placenta are found in spite of nephritis, sometimes the death of the child has already occurred before irritation of the kidneys presents itself, or the changes in the placenta are of an earlier date than the albuminuria. Finally it is unexplainable that, in cases of twins, one placenta is found diseased and the other normal. The proper final explanation raises still great difficulties and must be reserved for further investigations.—*American Journal of Obstetrics*, October, 1888.

PICROADONIDIN, THE ACTIVE PRINCIPLE OF ADONIS VERNALIS.—PROF. PODVYSOTSKI, of Kazan, publishes in the *Meditinskoe Obozrénie* some researches upon the active principle existing in *Adonis vernalis*. He finds by chemical analyses of the entire plant there is an amorphous substance of the nature of a glucoside (picroadonidin) which is the active principle, but that together with this there are present an orange-yellow substance (adonido-quercetin), a sugar (adonido-dulcittum), which crystallizes in beautiful prisms, a physio-

logically inactive glucoside, and an acid already pretty well known, and existing in *aconitum napellus* and some species of *equisetum*, and therefore called aconitic or equisetetic acid, $C_6H_5O_6$. Hitherto all attempts to isolate the active principle of *Adonis vernalis* have resulted in mixtures of the several substances named in various preparations, so it is not surprising that the so-called adonidins of different observers presented very dissimilar properties. Picroadonidin has an extremely bitter taste. It is easily soluble in water and alcohol, and slightly so in chloroform. It possesses all the physiological properties of the plant itself in a very high degree.—*Lancet*, October 13, 1888.

USE OF ANTIPYRIN IN THE NASAL PASSAGES.—DR. F. WHITEHILL HINKEL, of Buffalo, draws the following conclusions from clinical experience:

1. A solution of antipyrin possesses hæmostatic properties when sprayed into the nose, though not superior to cocaine.

2. Antipyrin in about 4 per cent. solution may be used upon the nasal mucous membrane with temporary relief to occlusion from engorgement of the turbinates, and with sedative effects upon irritable states.

3. It is most effective where the element of irritation exceeds that of inflammation.

4. It presents an advantage over cocaine in not producing local numbness and dryness, and in the absence of the general stimulating properties of cocaine, causing sleeplessness, headache, etc. In cases such as hay-fever, where an agent of relief is used for long periods, antipyrin as a nasal spray is less likely than cocaine to produce constitutional disturbance or to lead to a "habit."

5. Antipyrin presents the disadvantage of causing more or less severe smarting, and of being unequal to the relief of severe inflammation or extreme occlusion of the nares.

6. Its antiseptic and stimulant properties will probably make it serviceable as an application to fresh wounds and to granulations and ulcerations in the nasal chambers.

7. Combined with cocaine, it increases the local action of the latter, enabling it to be used in weaker solution.—*N. Y. Med. Journ.*, Oct. 20, '88.

INJECTIONS OF WARM WATER IN EPITHELIOMA OF THE CERVIX.—DE TORNERY draws the following conclusions:

1. Injections of warm water at 102.2° to 104° F., for about half an hour, twice a day, morning and evening, disinfect the vagina, cleanse it, and considerably diminish the ichorous discharge.

2. These injections diminish the loss of blood, and improve the general health.

3. In the majority of cases the pains are diminished, so that there is less need of injections of morphine.—*France Médicale*, No. 86, 1888.

Address

JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION,
No. 65 RANDOLPH STREET,
CHICAGO, ILLINOIS.

All members of the Association should send their Annual *Dues* to the *Treasurer*, Richard J. Dunglison, M.D., Lock Box 1274, Philadelphia, Pa.

LONDON OFFICE, 57 AND 59 LUDGATE HILL.

SATURDAY, NOVEMBER 3, 1888.

"HOW FAR CAN LEGISLATION AID IN MAINTAINING A PROPER STANDARD OF MEDICAL EDUCATION?"

Such is the title of a paper read before the American Social Science Association, at the annual meeting held at Saratoga on September 5, by Mr. W. A. PURRINGTON, Counsel of the Medical Society of the County of New York. This paper, says the author, "is a statement of what I conceive to be general principles and fair inferences from an experience of some years, as counsel of the medical societies of the State and County of New York, in drafting and securing the enactment of the present by no means perfect medical statute of the State, and enforcing in the County of New York obedience to its provisions."

At the beginning of last summer Mr. Purrington sent out a number of circular letters of inquiry upon the general topic of medical legislation; "almost every reply to the circulars expressed approval of some system of regulating by statute the practice of medicine; and the opinion was also strongly expressed that such legislation as had been already, crude and imperfect though it is, has perceptibly improved the standard of medical education."

At the beginning of his paper the author lays down certain postulates. In the first place, he says, such legislation as he was about to consider was considered by the courts as both constitutional and highly desirable. In the second place, the principle, and the only principle upon which such legislation can be justified is *salus populi*,—the

principle of security, of self-protection against fraud and ignorance. It is not the principle of protection for the medical profession that justifies such legislation, but protection of the public. Mr. Purrington goes on to speak of the evils of charlatanry, and then of the legal remedies against the immoralities of quackery, and of the existing statutes that recognize the diploma as conferring the right to practice. "While it may be perfectly true," he says, "that the probabilities are greatly in favor of a beneficial result from these laws in limiting the number of uneducated practitioners of physic, it is also quite as true that a fictitious value is given by such legislation to a mere piece of parchment, and a standard set which cannot be higher than that of the poorest college whose diploma is recognized as a license; and it is quite possible that in many cases persons of fair attainments acquired through extra-collegiate study may be debarred, temporarily at all events, from a right possessed by a far more ignorant graduate of some contemptible school incorporated by a too complaisant Legislature." It is seen, then, that a statute must not only be right in its purposes, but also that it must neither work greater evil than it prevents, nor be impracticable of enforcement. The chief purpose of legislators in times past, Mr. Purrington points out, was the punishment and remedy of evil already committed; but the tendency of modern times is towards prevention—to use a homely simile, locking the door before the thief gets in and the property is taken out.

Mr. Purrington now goes on to discuss the question, within what limits is it wise to exercise the police power of the State to regulate the practice of medicine, and how far can its exercise aid in maintaining a proper standard of medical education? The law, says Mr. Purrington, has nothing to do with medical theories. "The utmost it can do successfully is to prescribe that none shall practice medicine except persons educated in those branches of science that all admit are essential to an understanding of morbid conditions of our species, and possessed besides of a fair general education. It cannot prohibit the practice of sectarian medicine and such delusions as the mind-cure and Christian science, for this would be an assumption by the law to prescribe what system of healing shall be followed; and it might as reasonably command—as, indeed, I believe it does in Mormonism—that all the sick should be treated by

anointing with oil in conjunction with prayer by the elders." Certainly, coming from one learned in the law, this is a surprising statement; and when we remember the principle upon which he says medical legislation is justified—*salus populi*—it does not fall short of being paradoxical. True, the law cannot prohibit theories and opinions of mind-curers and Christian scientists; it cannot prohibit thought; but to say that it cannot prohibit certain practices is a very different matter. Mr. Purrington continues: "If a man who has passed his examinations in such branches as above indicated (the various branches of medicine) shall conclude to adhere uniformly in practice to the doctrines of *similia* or of *contraria*, or even to the profundities of Mumbo Jumbo, or mind-cure, the law cannot prevent him. For his errors, he will be liable always in damages, no matter what system he adopts; and with that we must be content." Hence we must conclude that should the makers of the law, the people, finally come to the conclusion that the "profundities of Mumbo Jumbo" are dangerous, and subversive of the very thing that medical legislation must conserve—*salus populi*—it cannot prohibit such practices, but must be content with holding the practitioner in damages for his errors!

The author, in speaking of the ways in which legislation can aid in maintaining a proper standard of medical education, points out that it can do so chiefly by vesting the licensing power in a central Board of Medical Examiners, and says that the law should not recognize any diploma as of itself conferring the right to practice medicine; the possession of a diploma may be required as antecedent to examination, but it should not be allowed to take the place of such examination. "It is to the interest not only of the public, but of every medical college of high standard, that the diplomas of what have become known as 'diploma mills' shall be deprived of the licensing power, which is their sole value." Legislation, he thinks, may aid in raising the standard by fixing a minimum age under which no one shall be allowed to practice medicine; by requiring a fixed term of study of certainly not less than two graded years (did he mean not less than *three* years?); by requiring proof by examination or certificate that each candidate for license had studied before beginning his professional career at least those branches of a gen-

eral education in which law students are examined in this State (New York) before they commence their legal studies (the reader will of course note the very close relationship between the practice of law and that of medicine, and the similarity of the preliminary educations required for them!); by declaring that no medical school—including in the terms schools of dentistry, pharmacy, and mid-wifery—shall be incorporated by special act, and providing a general law for the incorporation of such schools only upon proof made of the possession by the incorporators of sufficient capital—not less than a hundred thousand dollars—and teaching plant to justify the belief that the school will be capable of exercising faithfully its franchises; the provision of a minimum course of medical study. We cannot agree with Mr. Purrington that the regulation of all details of examinations should be left to the board of examiners. A good law should require that the colleges hold certain examinations during the course and at the expiration of the term of medical study, besides the examination for license by the medical examining board. Nor does the author give any good reason why "it would be most wise to omit any examination in those obscure topics of therapeutics and materia medica."

We have not space for more extended consideration of this paper. Coming from a member of the bar, and the Counsel to the New York County Medical Society, it will most probably have much weight, and is worthy of consideration. The paper seems, unfortunately, to have been prepared hastily; there is nothing to show that the medical laws of other countries had been carefully studied, with the view of grafting their better elements into our laws if possible. "There is too much of the *laissez faire* policy exhibited," is the criticism of a prominent member of the Chicago Bar. With our best colleges demanding three years, and the colleges of foreign countries demanding four years of medical study, it is very late to speak of "not less than two graded years." We hope to see the day when medical legislation in this country will have gone farther in raising the standard of medical education in this country than the point beyond which the author says it would not be wise for the legislation to go.

DR. SOMMER has been appointed Prof. Budge's successor to the Chair of Anatomy at Greifswald.

THE PATHOLOGY OF PERNICIOUS ANÆMIA.

DR. WILLIAM HUNTER has recently concluded, in the *Lancet*, a most interesting paper on this subject, being the record of a series of investigations made with the object of throwing some light on the pathology of the disease called *progressive anæmia* or *pernicious anæmia*. These investigations were partly clinical and partly pathological. It must be said that Dr. Hunter has occupied himself with a most important task, when we remember the interest taken in this affection since Addison called attention to it.

Space is wanting for more than a summary of the results of the investigations, and some short comment upon them. In the first place, he concludes, pernicious anæmia is to be regarded as a special disease, both clinically and pathologically. It constitutes a distinct variety of idiopathic anæmia. *Second*. Its essential pathological feature is an excessive destruction of blood. *Third*. The most important pathological change to be found is the presence of a large excess of iron in the liver. *Fourth*. This condition of the liver serves at once to distinguish pernicious anæmia *post-mortem* from all varieties of *symptomatic* anæmia, as also from the anæmia resulting from the loss of blood. *Fifth*. The blood-destruction characteristic of this form of anæmia differs both in its nature and its seats from that found in malaria, in paroxysmal hæmoglobinuria, and other forms of hæmoglobinuria. *Sixth*. The view can no longer be held that the occurrence of *hæmoglobinuria* simply depends on the quantity of hæmoglobin set free. *Seventh*. On the contrary, the *seat* of the destruction and the *form assumed by the hæmoglobin* on being set free are important conditions regulating the presence or absence of hæmoglobinuria in any case in which an excessive disintegration of corpuscles has occurred. *Eighth*. In paroxysmal hæmoglobinuria the disintegration of corpuscles occurs in the general circulation, and is due to the rapid dissolution of the red corpuscles. *Ninth*. In pernicious anæmia the seat of disintegration is chiefly the portal circulation, more especially that portion of it contained within the spleen and liver, and the destruction is affected by the action of certain poisonous agents, probably of a cadaveric nature, absorbed from the intestinal tract.

Thus it will be seen that Dr. Hunter's investigations seriously disturb some existing illusions

in regard to the pathology of pernicious anæmia—among others, that the affection is dependent upon some impairment of the normal process of blood-formation. The investigations show, also, that pernicious anæmia is quite distinct from the anæmias secondary to and due to wasting diseases, loss of blood, or diseases of the organs of nutrition.

LABORATORIES FOR BACTERIOLOGICAL AND ORIGINAL INVESTIGATION.

The Trustees of the Hoagland Laboratory announce to the medical profession of Brooklyn, N. Y., the completion and equipment for practical work of their laboratory at the corner of Henry and Pacific streets. Dr. Geo. M. Sternberg, the Director, being absent for further prosecution of his investigation into the causes of yellow fever, by order of the President, the course of lectures on bacteriology previously announced will be postponed until his return. But George T. Kemp, Ph.D., Johns Hopkins University, has been appointed as Associate in Bacteriology and Physiology, and with his assistance practical instruction in bacteriology will be given during Winter and Spring.

With fairly well-equipped laboratories for instruction and practical research in bacteriology, physiology and pathology at the Johns Hopkins, Baltimore; at the University, Pennsylvania; the Carnegie, New York; the Hoagland, Brooklyn; the Harvard, Boston; the Chicago Medical College, Chicago; and some others, it can no longer be claimed that American students are obliged to cross the Atlantic either for instruction in these departments or for facilities for prosecuting original researches.

AMERICAN MEDICAL ASSOCIATION.

The Fortieth Annual Meeting of this Association will be held at Newport, R. I., on Tuesday, the 25th of June, 1889, instead of the *first* Tuesday in June, as appointed at the meeting in Cincinnati, for the reasons previously mentioned in THE JOURNAL. Next year will also be the 25th anniversary of the settlement of Newport, and all circumstances favor a meeting of the Association of unusual interest. The Rhode Island State Society is cordially coöperating with the Local Committee of Arrangements. We are informed that acceptances have been received from each of the

gentlemen elected to deliver the general addresses at the meeting in Newport. The Address in Medicine will be given by Professor Wm. Pepper, of Philadelphia; the Address in Surgery by Professor P. S. Connor, of Cincinnati; and the Address in State Medicine by Professor W. H. Welch, of Baltimore.

The following constitute the Local Committee of Arrangements: H. R. Storer, Chairman; W. Thornton Parker, Secretary; C. F. Barker, M. E. Baldwin, C. A. Brackett, J. P. Curley, P. F. Curley, J. P. Donovan, H. Ecroyd, Jr., V. M. Francis, T. A. Kenefick, G. M. Odell, F. H. Rankin, W. C. Rives, Jr., S. H. Sears, W. S. Sherman, H. E. Turner.

Associate Committee, appointed by the Rhode Island Medical Society, G. D. Hersey, W. H. Palmer, G. T. Swarts, all of Providence.

THE AMERICAN ACADEMY OF MEDICINE.

The next annual meeting of this Society is to be held in New York city on the 13th and 14th of November, 1888. It was organized twelve years since, for the very laudable purpose of encouraging a higher standard of literary and scientific education on the part of those who wish to enter upon the study of medicine. As one of the influences favoring the accomplishment of this object, a constitutional provision was adopted making the possession of the degree of Bachelor or Master of Arts, received after a systematic course of study, and of the degree of Doctor of Medicine, followed by three years of practice, necessary conditions of eligibility for membership in the Academy. It was the first, and we think the only attempt that has been made to sustain a National medical society, membership of which was to be restricted to such members of the profession as had received prior to commencing the study of medicine a true collegiate general education.

It was thought by its founders that the establishment of such a society would be a constant stimulus to the ambition of young men intending to enter the medical profession to so extend their general education as to render themselves eligible for membership in it; and that the reports, papers, and discussions elicited at the annual meetings would do much to develop and direct public sentiment on the subject of a higher standard of education and mental discipline as a preparation

for professional life. We hope the meeting in New York will be a large and profitable one, and that it will venture to select Chicago as its next place of annual meeting, or at least some city in the interior valley of the Continent.

PHYSIOLOGY IN THE PUBLIC SCHOOLS.

The readers of the *Century* will remember the very amusing article that appeared about a year ago from the pen of Samuel L. Clemens (Mark Twain), on the answers by public school children to examination questions in the public schools. Several months ago the *Popular Science Monthly*, in commenting on the abuses, educational and otherwise, of the public schools, declared that it was now demonstrated that the public school system should be abolished. In the August number of the *Popular Science Monthly* was an article by "a teacher" on "Physiology in the Public Schools," containing a large number of answers to examination questions. This article shows that physiology is as badly taught in the English as in American public schools, and that the misinformation in regard to the subject of study is due to too much learning by rote without comprehension of the meaning of the terms employed—and to bad teaching; possibly, also, to the fact that children are set at physiological studies at too early an age. And we must agree with what the *London Architect* says in regard to this matter: "These exercises may be thought amusing, but it should be borne in mind that every word represents more or less pain to some unhappy child in endeavoring to recall ponderous words which were without meaning. Education in sanitary matters is desirable, but, as it is at present conducted in public schools, it must injure children's minds by habituating them to the use of words which they cannot understand." Certainly, it is a serious blunder to lumber up the mind of a child with words that carry no meaning. The words of the Wise Man may be applicable here: "In all thy getting get *understanding*."

MEDICAL STATISTICS OF RUSSIA.

The Statistical Annual of the Russian Empire for 1884-85 gives the total population (of Russia in Europe?) as 108,787,235. In 1885 there were 4,597,441 births, with an excess of about 133,000 males; 129,700 children were illegitimate. The

deaths numbered 3,291,824, with an excess of females. The net increase in population was therefore 1,305,617. There were 42,946 violent deaths, including 3,450 homicides and 2,494 suicides.

The deaths from various diseases were: 153,559 from febrile affections; 11,506 from small-pox; 8,505 from scarlatina; 19,320 from diphtheria, 8,024 from measles; 2,123 from pertussis, and 28 from *cholera nostras*. Of 589,274 cases of zymotic disease, 86,229 terminated fatally.

The number of hospitals in Russia in 1884-85 was 867, containing 57,825 beds. To these must be added 17 hospitals containing 8,584 beds for the use of foreigners.

The number of cases of syphilis in Russia in the period mentioned was 399,951. The number of vaccinations practiced was 2,300,404.

The medical *personnel* included, in 1884, 3,302 sanitary physicians, 7,653 physicians of inferior rank, and 3,170 midwives. The eight universities had 4,459 students of medicine.

One is forcibly struck with the insufficiency of the number of medical men for so large a population, with the small number of medical schools, the very large number of medical students as compared with the number of practitioners, and with the value that the Russian Government seems to attach to vital statistics. In spite of their small number the medical profession of Russia have added much that is valuable to the literature of medicine, and would have added much more that is accessible but for their apparently insurmountable language.

EDITORIAL NOTES.

PROFESSOR G. RUGE, of Heidelberg, has been elected Professor of Anatomy in the University of Amsterdam.

A MORGUE FOR LONDON.—A French contemporary states that there is a project for the establishment in London of a morgue similar to that in Paris.

DR. HENRY GRADLE, of this city, we are pleased to say, was acquitted of malpractice in the recent suit against him. We hope to have an account of the case in an early issue.

DR. JOSEPH SARGENT, a well-known practitioner of Worcester, Mass., for almost half a century, died of pneumonia on October 13. He

was born in 1815, and graduated from Harvard Medical School in 1837. He was a man of great public spirit, and his loss will be severely felt by both the profession and the public.

"LAPAROTOMY IN THE TREATMENT OF INTRAPERITONEAL INJURIES," an address delivered before the Medical Society of London by SIR WILLIAM MACCORMAC, has been translated into German by Dr. Thambayn, Volkmann's assistant, and is issued as one of the numbers of Volkmann's *Sammlung Klinischer Vorträge*.

DURING the recent visit of DR. MORRIS H. HENRY, of New York, to Turkey, he was most kindly treated by the surgeons of Constantinople, and was honored by His Imperial Highness, the Sultan, with the Imperial Order Commander de l'Osmanie, and a present of jewels. This is a gratifying acknowledgment of the interest taken by foreigners in American surgery.

PHARMACY IN RUSSIA is now receiving the attention of the Government. A plan is being prepared by which the status and qualifications of a Master in Pharmacy will be equal to that of the Russian Doctor of Medicine. The Master in Pharmacy will have to spend eight semesters at a university. The two sexes are to have equal privileges. The *Apothekerverein* of Germany has set on foot a movement looking to the same ends.

GYNÆCOLOGICAL SOCIETY OF CHICAGO.—At the annual meeting of this Society, held at the Richelieu Hotel on October 19, the retiring President, Dr. Henry T. Byford, delivered his Annual Address, and the following officers were elected: President, Dr. Charles T. Parkes; First Vice-President, Dr. Edmund J. Doering; Second Vice-President, Dr. E. C. Dudley; Editor, Dr. W. W. Jaggard; Secretary, Dr. Edward Warren Sawyer; Treasurer, Dr. Frank E. Waxham.

OHIO STATE SANITARY ASSOCIATION.—The Sixth Annual Meeting of this Association will be held in the City Hall, Canton, Ohio, November 14th and 15th, 1888. A full and important programme of work has been arranged for the two days' session. The first session will commence at 10 A.M. of the 14th, and the closing meeting will begin at 1 P.M. of the 15th. Arrangements have been made for commutation of railroad fares, but for further information address the Secretary, R. Harvey Reed, M.D., Mansfield, Ohio.

SOCIETY PROCEEDINGS.

Philadelphia County Medical Society.

*Stated Meeting, September 12, 1888.*THE PRESIDENT, J. SOLIS COHEN, M.D.,
IN THE CHAIR.DR. J. SOLIS-COHEN read a paper on
SYPHILIS OF THE LARYNX, TRACHEA, AND
BRONCHI.

Syphilitic processes not only injure the structural integrity of the larynx and trachea directly but, by their location in the regions occupied by the origin and course of nerve supply, they lead to denutrition of the tissues generally, and to serious motor impairments of the muscles of the larynx. The distinctions between secondary and tertiary syphilis, as manifested in the upper air-passages, are so irregular and uncertain, that many writers prefer the terms recent and tardy. In fact, however, secondary lesions are sometimes tardy and tertiary lesions sometimes precocious. Secondary lesions are sometimes present as the sole manifestation of that period. Sometimes they precede cutaneous manifestations. Most frequently they occur in subjects already affected with what are known as mucous patches in other portions of mucous membrane, or with early cutaneous syphilides.

Pathology.—The earliest and far most frequent manifestations are subacute and diffusely hyperæmic conditions of portions of the mucous membrane, of varied extent and intensity; an erythema with turgescence, but without hypersecretion, occurring within from six to ten weeks after infection. The affected surface exhibits at first the usual rose-color of congestion, but, as stasis, infiltrations, and hæmic transudations occur, it becomes more or less livid in patches which present mottled or flaky discolorations. Superficial erosions often ensue. Occasionally deep-seated ulceration occurs. Sometimes paresis of the muscles of the larynx is produced. The erosions may be due simply to denutrition of epithelium from mere pressure by infiltrations, or to disintegration of a characteristic proliferative lesion known as the papule or mucous patch, by some termed broad condyloma, a product, according to Virchow, of the same histological character as the indurated chancre and the various gummy formations, namely, an infiltration of tissue with nucleated embryonic cells. These papules are characteristic, but by no means frequent syphilitic products in the larynx, and are so infrequent in the trachea that their occurrence there is denied by authorities the very highest. They are multiple recurrent lesions, almost invariably associated with mucous patches on other mucous membranes; usually lasting from

three to five weeks, and sometimes much longer. They are observed from within a few weeks to a few months after infection; sometimes earlier, occasionally as late as eighteen months. They are far the more frequent in tuberculous subjects who have contracted syphilis.

The erosions which occur on the surface of the papules or on simply erythematous mucous membranes are usually superficial, but may extend through the mucous membrane and beneath it, under bad hygienic conditions. Under slight provocative exposures to cold and wet, fluxionary œdema sometimes takes place in their vicinity, occasionally to such an extent as to be menacing to life. The epiglottis often becomes very much thickened, the vocal bands thickened and dentedly eroded. There seems to be no tendency for secondary lesions to extend from the larynx to the trachea.

Tertiary lesions come under notice most frequently in the stage of ulceration, usually following the liquefaction of gummous nodules, gummous infiltrations, or true gummata, as may be. The epiglottis is the most frequent seat; so frequent, that its lingual and lateral ulceration has been erroneously deemed pathognomonic of syphilis; but destructive lesions may occur in every portion of the larynx. The ulceration is both serpiginous and deep-seated, and, while more commonly unilateral, there seems practically to be little limit to its phagedenic destructive ravages under unfavorable conditions, as it destroys and penetrates all the tissues, soft and cartilaginous. Slight provocation may produce fluxionary œdema in this stage also, which may be of the most serious character. Serious hæmorrhages may occur from penetration of blood-vessels, and apnoea may ensue from incarceration of fragments of necrosed cartilages and soft tissues. Ulceration may be attended with proliferative vegetations which may occlude the air passages. Superficial ulceration may heal with moderate cicatrization which eventually becomes hardly noticeable. Deep and extensive ulcerations heal under peculiar whitish, lustrous, stellate, retractile cicatrices, similar to those which follow burns. Instead of cicatrizations, adhesions may take place between contiguous raw surfaces, and strictures of various kinds be formed in consequence.

The gummous lesions preceding these ulcerations are of three kinds: small gummous multiple nodules or nodular syphilides; diffuse gummous infiltration; and gummata proper, usually isolated.

Small gummous nodules (nodular syphilide, Lewin) vary in size from that of small bird-shot to that of peas, and are usually grouped in well-defined determinate figures in the body of the mucous membrane, and often so contiguous as to appear confluent. Gummata proper, present as firm hemispherical nodules or tumors, from the size of peas to that of cherries or almonds, and

sometimes much larger, in the connective tissue beneath the mucous membrane; usually uniform in outline, sometimes lobulated; undischarged or reddish at the base, yellowish at the summit. Gummous infiltrations present as more or less longitudinal or more diffuse submucous thickenings corrugating the surface of the mucous membranes. All these products may undergo absorption.

When not absorbed, gummous nodules undergo purulent liquefaction. At this time they become softer, and more yellowish at the summit, the mucous membrane at the base becoming more inflamed and thickened, the whole mass looking not unlike a furuncle. The summit becomes perforated, and gives exit to thickened, yellow pus, with granular admixture of debris at first. The orifice rapidly enlarges by ulceration until it becomes fully as large in circumference as the nodule was, or larger, and readily coalesces with ulcerations from contiguous nodules. The ulceration extends in depth until it occupies the entire volume of the nodules, and may then penetrate all the tissues beneath, even to the perichondrium and cartilage.

The ulceration of the nodulous syphilitic, as studied in a series of cases by Lewin, is said to take place more from periphery to centre than the reverse, being shallow at first, and then gradually deepening. The ulcer is round, depressed, and sharply bordered. Its bed is covered with a secretion which, from previous fatty degeneration, or purulent metamorphosis, is either thickish, or nearly lardaceous, or composed of purulent detritus.

The more longitudinal and the diffuser gummous infiltrations undergo liquefactive ulceration much more slowly; but the subsequent ulceration, when unchecked, extends much more rapidly, and becomes more readily serpiginous and phagedenic; so that, coalescing with similar conditions in the vicinity, large surfaces in continuity become involved in its ravages. As it extends in superficiality it penetrates slowly in depth until it also involves the deeper structures close to the perichondrium, and sometimes to the cartilage. Ulceration varies in rapidity, extent and penetration according to the succulence or resistance of the tissues contiguous. The ulceration from diffuse gummous infiltration is preceded, according to Lewin, by extensive fatty degeneration of its surface, which gives it an almost grayish-white tinge. This is soon followed by actual defects which, at first shallow, increase in depth, and gradually penetrate to the perichondrium and the cartilage. These ulcers are characterized, like those from the nodules, by sharp definite circumscription, and by their being surrounded with an inflammatory swollen zone. They appear often as though a piece of swollen tissue had been cut out. The edges are often beset with slight crenations, which give them a gnawed appearance, but are never undermined; and their bottom is covered with a yellowish-white adherent mass, com-

posed of pus, fatty detritus, and shreds of tissue. Gummata proper sometimes remain unchanged for prolonged periods. When they undergo degenerative metamorphosis there is formed, according to Lewin, only the characteristic viscid fluid, suppuration being exceptional. Ulceration takes place, however, in some instances, and penetrates deeply into the tissues beneath, as in the other two forms. Under unfavorable hygienic conditions of system, or of surroundings, the phagedenic ravages may become uncontrollable. They have been known to attack an artificial opening made to prevent suffocation by a gumma (Holden, *New York Medical Journal*, January 29, 1887).

Perichondritis and chondritis being set up after either form, the ulceration may penetrate the cartilage to the tissues external, forming a perichondrial abscess, which ruptures externally by a more or less circuitous route, whence the fragments of dead tissues are discharged.

Taken in point of frequency the cartilaginous structures seem to be vulnerable in the order following: epiglottis, posterior vocal processes, arytenoids, supra-arytenoids, cricoid, cuneiform and thyroid. Coming to the softer parts, the vocal bands are attacked next in frequency to the epiglottis, the left band far more frequently than the right; the interior supraglottic walls of the larynx, the aryepiglottic folds, the interarytenoid fold, the posterior wall, the ventricular bands, the subglottic walls of the larynx, the exterior of the soft parts in the pyriform sinus. When the cartilages are attacked, whether primitively or consecutively, the chain of morbid phenomena is perichondritis, chondritis, calcification, caries, necrosis, and elimination of sequestra in crumbled masses and in fragments. The elimination of dead cartilages may consume months, and even years. It usually takes place by the interior route, occasionally by the exterior. In both instances abscess and fistula are formed, and elimination of large fragments by the interior route sometimes produces suffocative paroxysms, and occasionally, actual suffocation.

The epiglottis, as repeatedly noted, is especially vulnerable to the syphilitic process, and every variety of lesion possible may ensue in any extent, from insignificant erosion to complete destruction, the character of the lesion depending upon that of the structure destroyed. It is this, as pointed out by Seiler, which gives such an irregular conformation to the epiglottis when its glands have been destroyed.

Exulceration of the entire mucous membrane of the edge reveals the exposed cartilaginous structure as a yellowish-white stripe imbedded between two thickened masses of spongy-looking tissue. Ulceration of the cartilage often commences at the anterior surface in the form of a round ulcer with thickened excavated edges. Destructive ulceration usually progresses from the side and from the

edge. When the valve is only partially destroyed its remains may present two or more irregular fragments separated by fissures of varying depth, or a single fragment of any breadth, from a small stripe to nearly the entire bulk.

When totally destroyed the orifice of the larynx is separated from the post-lingual sulcus by a more or less irregular ridge of ulcerated tissue, which, after cicatrization, presents as a pale, deformed stump. This, however, does not, as a rule, prevent glutition, and in some instances does not even interfere with it; the occlusion of the larynx being effected by the base of the tongue, on the one hand, and by close approximation of the ventricular bands and sphincter-like approximation of the aryepiglottic folds, on the other.

The other cartilages, when the subject of destructive progressive ulceration, are macerated out of their investments, as it were. The ulcerative process extends into the cartilage, surrounding it, if a small one, or circumscribing a portion of it, if it be a large one. The cartilage then perishes by necrosis, is laid bare and becomes detached from its connections, in some instances remaining entangled in a sort of pocket scooped out of the soft tissues. The necrosed cartilage finally breaks through to the interior and is usually discharged by expectoration. If it be situated below the glottis, paroxysms of suffocation may ensue, or even actual apnoea, as from any other foreign body. Exfoliations of the cricoid cartilage are the most frequent source of these untoward results, which, however, sometimes ensue from exfoliations of the thyroid.

The ulcerative process sometimes penetrates blood-vessels and hæmorrhage follows. Such hæmorrhage has been known to terminate fatally (Türk, *Op. cit.*, p. 413, illustrated).

The vocal bands frequently sustain permanent lesion varying from minute losses of substance to entire destruction. Transversal dentated erosion of the border is not uncommon, and detachment from the posterior vocal processes not infrequent. Sometimes irregular papillary proliferations take place, forming mobile, projecting, pyramidal, or irregular dendritic vegetations, which project like soft, mobile stalactites into the interior, and which are large enough, in exceptional instances, to demand operative interference. Similar conditions and productions may prevail with the ventricular bands. Superficial ulcerations may heal with moderate cicatrization, which eventually becomes hardly noticeable. In deep and extensive ulcerations, when cicatrization occurs, a peculiar lustrous, whitish, stellate, contractile cicatrix is formed, similar to the syphilitic cicatrix in other mucous membranes. Instead of cicatrization, adhesions often take place between ulcerated surfaces, and thus a variety of injurious morbid conditions occur. The vocal bands may become united by a broad fibrinous band stretching between

them, or by a similar obturator formed of their thickened and distended mucous membrane. The membranous web thus formed between the vocal bands usually unites them for a variable distance, commencing at the commissure; the posterior border of the structure being crescentic in outline. Exceptionally the cords may become involved their entire length, with an orifice in the central portion of the web (Navratil).

This membranous union has been known to take place in six days (Rossbach: Langenbeck *Archives*, vol. xiv). In a case watched by Sommerbrodt (*Berlin. klin. Woch.*, April 1, 1878), the anterior third united in fourteen days, and the union of the bands was complete in six weeks. In other cases the vocal bands become united without any membrane intervention.

Other adhesions sometimes take place which may seriously impair glutition, phonation, and even respiration. These comprise depression of the epiglottis to one side or the other, or to an aryepiglottic fold, and preventing proper closure of the valve or complete elevation; adhesion of the epiglottis to either lateral pharyngeal wall; adhesion of ventricular to vocal band, sometimes preventing closure of the glottis, and often producing a shrill, weak, piping voice; adhesions anteriorly of the two vocal bands or of the two ventricular bands; adhesions of the inner surfaces of the mucous membrane of the arytenoid cartilages, so as to fix the vocal bands immovably in the median position. Other results of syphilitic laryngitis are hypertrophies, diffuse and discrete, of mucous membrane, connective tissues, or muscular substance, and consequent stricture, varying in extent, locality, and interference with function; myopathic paralysis; muscular atrophy and morbid growths.

Perichondritis or chondritis, whether following ulcerative destruction of the soft tissues or preceding it, usually excites considerable fibrinous infiltration into the adjacent submucous connective tissue, producing a chronic fibrinous œdema. When extensive, this produces suffocative symptoms, and may threaten asphyxia. Sometimes the submucous infiltrations become organized and transformed into dense fibrous tissues incapable of undergoing absorption, and thus they produce deformity, occlusion of the larynx, and stricture. The strictures are often incapable of yielding to systematic dilatation, even when instituted early; and hence tracheotomy is usually necessary to provide artificial means for respiration below the seat of obstruction. After tracheotomy, the process may progress to complete obliteration.

These strictures are of the most varying form and calibre, some of them distorting the configuration of the interior of the larynx almost out of recognition. Fortunately, most of them occur in the supra-glottic region, where they are far more accessible to effective treatment.

Lesions of either soft tissues or cartilage in the neighborhood of the important crico-arytenoid articulations excite non-specific inflammation of the joint which may produce true or false ankylosis. Syphilis is probably the most frequent cause of this lesion. When the specific process invades the joint, the ligaments and perichondrium suffer, and true ankylosis, or luxation, or disarticulation, and even discharge of the arytenoid and supra-arytenoid cartilages, may ensue.

In the latter stages of unrestrained lesion, the cachexia is much the same as in analogous advanced stages of tuberculosis.

Myopathic paralyses of the muscles of the larynx may occur in the later periods of secondary syphilis, and at any period of tertiary syphilis. They are most frequently unilateral, the left side being affected far oftener than the right. The onset is often sudden or acute, following severe or sudden exposure to cold and dampness. The paralysis often affects the dilator muscles, and bilateral paralysis of the dilators is not infrequent. Paralyses of the arytenoid muscle and of the entire constrictor group are the most frequent varieties. These paralyses differ in their pathological origin from other examples of paralysis in syphilis, which are due, respectively, to compression of the tract of the nerve-supply by diseased tracheo-bronchial glands or other structure, and to neural or cerebral lesions which present in the latter stages of the confirmed dyscrasia.

Tertiary lesions of the trachea are first observed so very frequently in the stage of ulceration, that it had been assumed that tertiary syphilis of the trachea always produces ulceration (Vierling). Schech and others have reported instances of resorption of gummata under specific medication. The clinical tendency, however, is to ulceration. Tracheal ulcerative lesions are sometimes unassociated with lesions elsewhere in the aerial tract. Much more commonly they are found associated with similar lesions in the larynx, in the bronchi, or in both.

Pharyngeal syphilis exists in thirty out of forty-six, collated by Vierling, and pulmonary syphilis in six out of fifty (Schech). They are often found associated with additional syphilitic lesions at a distance. In a large proportion of instances a primitive bronchus is affected, the left one the more frequently; in some, both primitive bronchi; in a few, the smaller ramifications (Vierling); and, exceptionally, even the minutest (Lancereaux). In some instances syphilitic lesion is confined to the bronchia (five cases, by Vierling). The upper portion of the trachea suffers most when the larynx is involved; the lower portion, when the disease is isolated or associated with syphilis of the bronchi. In some instances the middle portion alone suffers (Vigla and Charnal, Berger, Mackenzie, of Baltimore, Semon); exceptionally, the two extremities, with

complete conservation of the middle portion (Tessier, cited by Rey).

When not occurring in direct continuity with similar lesion in the larynx, the most frequent seat of ulceration is in the anterior surface of the lower portion of the trachea just above the bifurcation whence it extends upward, or in patches continuously sometimes as far as the cricoid cartilage; sometimes almost completely around the interior in periphery, occasionally completely around. Multiple perichondritis is easily set up and results in abscess, denudation of cartilage, calcification, caries, and necrosis. Portions of dead cartilage are sometimes coughed up in fragments. Sometimes semi-detached portions project into the interior and interfere seriously with respiration and with expectoration. The ulceration usually begins in a number of small ulcers which extend in depth and in periphery, baring the perichondrium, and causing portions of the cartilaginous rings, or entire rings, to undergo denudation, necrosis, and exfoliation. Coalescence with similar ulcerating surfaces, or phagedenic extension sometimes produces very extensive ravages which may involve nearly the entire circumference of the trachea, and nearly, occasionally quiet, its entire length. Flaps of detached membrane sometimes fall over, producing valvular impediments to inspiration, or to expiration, according to the position of the attachments. The cicatrization of annular ulcerations produces stricture often so low down as to be beyond relief even from tracheotomy, the parts not being well adapted to respond to artificial dilatation. The strictures are irregularly ovoidal in shape, sometimes funnel shaped, and of varying thickness from a few lines to that of several rings.

These cicatrices may reduce the calibre of the trachea so considerably as to prevent respiration. Occlusion to the calibre of a crowquill is not uncommon, and still greater occlusion has been noted in some instances. Annular stricture at the bifurcation may become so great as barely to admit the passage of a delicate probe. (Obtulinowicz: *Cent. f. Chir.*, 1879, No. 7).

Irregular annular dilatation of the trachea is often produced by the pressure of the air current above the stricture and sometimes below it. Even dilatation of the bronchi has been noticed.

Projecting ridges of cicatricial tissue below the point of stricture are sometimes so located as to occlude the inferior orifice of a tracheal canula more or less, a point not sufficiently recognized, for it might be practicable in some instances to push a canula into a position which would allow its inferior extremity to pass the obstruction.

Stricture of the bronchi is rare. It affects the left bronchus more frequently (Verneinel *et al.*); sometimes the right one (Wilks, *et al.*); occasionally both (Virchow, *et al.*). The connective tissue around the strictured portions usually un-

dergoes permanent sclerotic proliferation. Sometimes there is great peritracheal sclerosis, sometimes none. The peritracheal glands may undergo great enlargement. All these conditions superadded to the internal stricture, may greatly increase stenosis.

Ulceration sometimes penetrates through the trachea producing abscess opening into the œsophagus or the mediastinum, the aorta (Rokitansky: *Path. An.*, Bd. III, p. 22; Wilks: *Trans. Path. Soc.*, London, 1865, p. 52), the pulmonary artery (Kelly: *Id.*, 1872, p. 45), or the vena cava (Turner: *Id.*, xxxvii, p. 117). In at least two instances of ulceration of the left bronchus the left branch of the pulmonary artery has been found perforated. (Vierling).

Inflammation around the trachea or bronchi sometimes produces adhesions to the œsophagus or to other tissues, which depresses the trachea and larynx and impairs their upward movements in glutton. Sometimes it produces peritracheal or tracheo-bronchial abscess. Abscess of bronchus, sometimes deeply seated, has occurred after tracheotomy, apparently as a result of too assiduous swabbing of the canula.

The lesions of hereditary syphilis are almost identical with those of the gumous infiltrations of tertiary syphilis. They sometimes appear very early. Ulcerations have been noticed in infants at 2 months of age (Parrot: *Prog. Méd.*, 1878, p. 653). Stricture from perichondritis has been noticed at the same age (Fränkel: *Wien. Med. Woch.*, 1868, No. 18; Parrot: *loc. cit.*).

Symptomatology.—The laryngeal symptoms of secondary syphilis are not characteristic. They are chiefly comprised in dissonant alterations of the voice, either hoarseness, dysphonia, and in some cases occasional or temporary aphonia. The hoarseness is supposed to have some peculiarity which has been termed *raucoedo syphilitica*, but this is not the case. In some instances it is simply due to catarrhal laryngitis, in others to paresis of one or more of the constrictor muscles, or possibly to paralysis of the tensors. Respiration is not affected except in those instances in which œdema occurs in such a position as to occlude the passage of air, when it will be announced by dyspnoea and stridulous respiration, the characteristic symptoms of that condition. Titillation and cough are not as frequent as in inflammations of other origin. In many instances there is no tickling and no cough, no pain and no dysphagia.

Dysphagia is not present unless there be œdema of the parts utilized or pressed upon in glutton.

In tertiary syphilis of the larynx the symptoms are usually those of impairment of phonation, followed in severe cases by dyspnoea and stridor also, chiefly inspiratory. The stridor is worse at night from inaction of the auxiliary muscles of respiration. Should the mechanical impediment to respiration increase, inspiratory depression of

the soft parts below the sternum takes place. If relief is not obtained, artificially or otherwise, asphyxia supervenes from imperfect aëration of the blood. Suffocation may occur suddenly from impaction of detached cartilage; but it is more frequently slow enough in its approaches to allow time for tracheotomy.

Titillation and cough are more frequent in the earlier stages than in secondary syphilis; but they diminish after ulceration has taken place, except in so far as they are produced from time to time by morbid products detained upon diseased and adjacent surfaces. Pain is infrequent before the period of ulceration; after that it may be severe, and radiate into the ears as in other ulcerative diseases. In the early stage there is no expectoration. The earliest expectoration is of collateral catarrhal products only. As ulceration progresses it becomes muco-purulent, and then purulent and sanguineo-purulent, and mixed with detritus according to the stage and location of the lesion.

If gangrene takes place the odor becomes fetid, and the expectoration contains fragments of dead soft and cartilaginous tissue, as may be.

Dysphagia ensues when the disease is in a locality to interfere with glutton, and odympagia when ulcerations have occurred in the same localities.

In tertiary syphilis of the trachea the symptoms affect mainly the function of respiration, the voice often remaining normal even when breathing is seriously embarrassed.

Pain along the course of the trachea, if constant, is indicative of lesion at that particular point. Cases may run their entire course without any special symptom, even in the presence of stricture of the trachea, and of the bronchi, and of extensive disorganization as revealed at the post-mortem examination.

In hereditary syphilis, the symptoms are sometimes congenital and may remain practically continuous for years. Respiration and phonation are both affected. The cry of the infant sometimes possesses a shrill metallic resonance which has been compared to that of a tin trumpet. Cough is more frequent in the child than in the adult. Glutton is often difficult and sometimes painful. Expectoration occurs in the suppurative stages when the child is old enough to expel the products, which by infants are swallowed or retained in the air passages. Laryngismus is a symptom of frequent occurrence in young children.

Etiology.—The probable condition attracting the manifestation of constitutional syphilis to the larynx is superficial catarrhal laryngitis from hereditary or acquired proclivity, or from exposure, or from abuse of tobacco, alcohol, or other indulgence, or from misuse of the voice. Such exposures cause more males to be affected than females, as there is no assignable sexual reason

for preponderance. Tracheal lesions, on the other hand, have been reported more frequently in females, probably because the laryngeal lesion is attended to more promptly by the male. Syphilitic disease often extends by continuity from the oropharyngeal region to the larynx, principally along the pharyngo-epiglottic fold to the epiglottis, and thence along the aryteno-epiglottic fold, and from the two structures to the interior. Hereditary syphilis has been observed in intra-uterine life (Monti: *Med. Times*, Phila., April 28, 1877, p. 336). Hereditary syphilis of the intensest character has been occasionally observed at a very early age, as in the case of an infant whose symptoms began with coryza in the tenth week of life, and terminated in death by suffocation from stenosis nineteen days later. Post-mortem, with examination, revealed in addition to syphilitic lesions in the liver, destructive perichondritis of cricoid and left arytenoid cartilage, and fatty degeneration of arytenoid and both posterior crico-arytenoid muscles and the left superior nerve (Fränkel: *Wien. med. Woch.*, 1868, Nos. 69, 70, cited by Ziemssen and by Mackenzie). Children less than a year of age often show laryngeal lesions of hereditary syphilis, and ulcerative lesions have been seen at two months of age (Parrot: *Prog. Méd.*, 1878, p. 635). Many cases occur in children but a few years of age, and sometimes the manifestations are deferred to the period of puberty or even later. Indeed, in opposition to the received opinion of syphilographers, I have reason to believe that in a few instances I have seen its manifestations delayed as late as the third and even the fourth decennium. True, in such instances as the latter it is quite possible that infection may have been acquired in some method unknown, without having been followed by any secondary manifestations, or that early hereditary manifestations may have escaped recognition. The secondary manifestations occur most frequently in adolescents and young adults. They appear most frequently at periods varying from a few weeks to a few months after infection, sometimes as late as the fourteenth or seventeenth month (Morgan). Tertiary lesions are most frequent at rather maturer ages, and occur occasionally in quite advanced life. They have been reported as early as the sixteenth month (Türk, op. cit.), and as late in their first appearance as the thirtieth (Türk), and even the fiftieth year (Mackenzie). Tracheo-bronchial tertiary lesions have been reported as appearing as early as the ninth month after infection, but these lesions are usually coincident with the laryngeal lesions when not immediately consecutive to them.

Most of the instances of tracheal syphilis occur in individuals whose employments expose them to irritation from dusts of various kinds (Vierling: *Deutsches Arch. f. klin. Med.*, 1878, Bd. 21).

(To be concluded.)

PUBLIC HEALTH.

DISINFECTION AND DISINFECTANTS.

Conclusions of the Committee on Disinfectants of the American Public Health Association.

The most useful agents for the destruction of spore-containing infectious material are:

1. *Fire*. Complete destruction by burning.
2. *Steam under pressure*. 105° C. (221° Fahr.) for ten minutes.

3. *Boiling in water* for half an hour.

4. *Chloride of lime*.¹ A 4 per cent. solution.

5. *Mercuric chloride*. A solution of 1:500.

For the destruction of infectious material which owes its infecting power to the presence of micro-organisms not containing spores, the committee recommends:

1. *Fire*. Complete destruction by burning.
2. *Boiling in water* for ten minutes.
3. *Dry Heat*. 110° C. (230° Fahr.) for two hours.

4. *Chloride of lime*. A 2 per cent. solution.

5. *Solution of chlorinated soda*.² A 10 per cent. solution.

6. *Mercuric Chloride*. A solution of 1:2,000.

7. *Carbolic acid*. A 5 per cent. solution.

8. *Sulphate of copper*. A 5 per cent. solution.

9. *Chloride of zinc*. A 10 per cent. solution.

10. *Sulphur dioxide*.³ Exposure for twelve hours to an atmosphere containing at least 4 volumes per cent. of this gas in presence of moisture.

The committee would make the following recommendations with reference to the practical application of these agents for disinfecting purposes:

FOR EXCRETA.

(a) In the sick-room:

1. Chloride of lime in solution, 4 per cent.

In the absence of spores:

2. Carbolic acid in solution, 5 per cent.

3. Sulphate of copper in solution, 5 per cent.

(b) In privy vaults:

1. Mercuric chloride in solution, 1:500.⁴

2. Carbolic acid in solution, 5 per cent.

(c) For the disinfection and deodorization of the surfaces of masses of organic material in privy vaults, etc.:

Chloride of lime in powder.

FOR CLOTHING, BEDDING, ETC.

(a) Soiled underclothing, bed-linen, etc.:

1. Destruction by fire, if of little value.

2. Boiling for at least half an hour.

¹ Should contain at least 25 per cent. of available chlorine.

² Should contain at least 3 per cent. of available chlorine.

³ This will require the combustion of between 3 and 4 pounds of sulphur for every 1,000 cubic feet of air space.

⁴ The addition of an equal quantity of potassium permanganate as a deodorant, and to give color to the solution, is to be recommended.

3. Immersion in a solution of mercuric chloride of the strength of 1:2,000 for four hours.

4. Immersion in a 2 per cent. solution of carbolic acid for four hours.

(b) Outer garments of wool or silk, and similar articles, which would be injured by immersion in boiling water or in a disinfecting solution :

1. Exposure in a suitable apparatus to a current of steam for ten minutes.

2. Exposure to dry heat at a temperature of 110° C. (230° Fahr.) for two hours.

(c) Mattresses and blankets soiled by the discharges of the sick :

1. Destruction by fire.

2. Exposure to super-heated steam, 105° C. (221° Fahr.) for ten minutes.

(Mattresses to have the cover removed or freely opened.)

3. Immersion in boiling water for half an hour.

FURNITURE AND ARTICLES OF WOOD, LEATHER, AND PORCELAIN.

Washing, several times repeated, with :

1. Solution of carbolic acid, 2 per cent.

FOR THE PERSON.

The hands and general surface of the body of attendants of the sick, and of convalescents, should be washed with :

1. Solution of chlorinated soda diluted with nine parts of water, 1:10.

2. Carbolic acid, 2 per cent. solution.

3. Mercuric chloride, 1:1,000.

FOR THE DEAD.

Envelop the body in a sheet thoroughly saturated with :

1. Chloride of lime in solution, 4 per cent.

2. Mercuric chloride in solution, 1:500.

3. Carbolic acid in solution, 5 per cent.

FOR THE SICK-ROOM AND HOSPITAL WARDS.

(a) While occupied, wash all surfaces with :

1. Mercuric chloride in solution, 1:1,000.

2. Carbolic acid in solution, 2 per cent.

(b) When vacated, fumigate with sulphur dioxide for twelve hours, burning at least three pounds of sulphur for every 1,000 cubic feet of air-space in the room ; then wash all surfaces with one of the above-mentioned disinfecting solutions, and afterward with soap and hot water ; finally throw open doors and windows, and ventilate freely.

FOR MERCHANDISE AND THE MAILS.

The disinfection of merchandise and the mails will only be required under exceptional circumstances ; free aeration will usually be sufficient. If disinfection seems necessary, fumigation with sulphur dioxide will be the only practicable method of accomplishing it without injury.

RAGS.

(a) Rags which have been used for wiping

away infectious discharges should at once be burned :

(b) Rags collected for the paper-makers during the prevalence of an epidemic should be disinfected before they are compressed in bales, by :

1. Exposure to super-heated steam of 105° C. (221° Fahr.) for ten minutes.

2. Immersion in boiling water for half an hour.

SHIPS.

(a) Infected ships at sea should be washed in every accessible place, and especially in the localities occupied by the sick, with :

1. Solution of mercuric chloride, 1:1,000.

2. Solution of carbolic acid, 2 per cent.

The bilge should be disinfected by the liberal use of a strong solution of mercuric chloride.

(b) Upon arrival at a quarantine station, an infected ship should at once be fumigated with sulphurous acid gas, using three pounds of sulphur for every 1,000 cubic feet of air-space ; the cargo should then be discharged on lighters ; a liberal supply of the concentrated solution of mercuric chloride (4 oz. to the gallon) should be thrown into the bilge, and at the end of twenty-four hours the bilge-water should be pumped out and replaced with pure sea-water : this should be repeated. A second fumigation, after the removal of the cargo, is recommended ; all accessible surfaces should be washed with one of the disinfecting solutions heretofore recommended, and subsequently with soap and hot water.

FOR RAILWAY CARS.

The directions given for the disinfection of dwellings, hospital wards, and ships, apply as well to infected railway cars. The treatment of excreta with a disinfectant, before they are scattered along the tracks, seems desirable at all times in view of the fact that they may contain infectious germs. During the prevalence of an epidemic of cholera this is imperative. For this purpose the standard solution of chloride of lime is recommended.

At the annual meeting of the Sanitary Council of the Mississippi Valley, held in New Orleans, La., March 10, 11, 1885, the following resolution was adopted :

Resolved, That the secretary request from the chairman of the Committee on Disinfectants, appointed at the last meeting of the American Public Health Association, a plain, practical paper on "Disinfection and Disinfectants," for popular use and distribution, to be furnished to the chairman or the special committee of this council on General Sanitation.

In compliance with this request a Preliminary Report was prepared, which has been quite widely circulated. This report having been made before the experimental researches of the committee were completed, and being a "preliminary report," was only intended to serve a temporary purpose ; but it has been thought best to revise it, and to introduce it into this our final report,

so that it may be available for distribution in a separate form if sanitary officials find it suitable for popular use.

DISINFECTION AND DISINFECTANTS.

The object of disinfection is to prevent the extension of infectious diseases by destroying the specific infectious material which gives rise to them. This is accomplished by the use of disinfectants.

There can be no partial disinfection of such material: either its infecting power is destroyed, or it is not. In the latter case there is a failure to disinfect. Nor can there be any disinfection in the absence of infectious material.

It has been proved for several kinds of infectious material, that its specific infecting power is due to the presence of living microorganisms, known in a general way as "disease germs;" and practical sanitation is now based upon the belief that the infecting agents in all kinds of infectious material are of this nature. Disinfection, therefore, consists essentially in the destruction of disease germs.

Popularly, the term disinfection is used in a much broader sense. Any chemical agent which destroys or masks bad odors, or which arrests putrefactive decomposition, is spoken of as a disinfectant. And in the absence of any infectious disease it is common to speak of disinfecting a foul cesspool, or bad smelling stable, or privy vault.

This popular use of the term has led to much misapprehension, and the agents which have been found to destroy bad odors—deodorizers—or to arrest putrefactive decomposition—antiseptics—have been confidently recommended and extensively used for the destruction of disease germs in the excreta of patients with cholera, typhoid fever, etc.

The injurious consequences which are likely to result from such misapprehension and misuse of the word disinfectant, will be appreciated when it is known that recent researches have demonstrated that many of the agents which have been found useful as deodorizers, or as antiseptics, are entirely without value, for the destruction of disease germs.

This is true, for example, as regards the sulphate of iron or copperas, a salt which has been extensively used with the idea that it is a valuable disinfectant. As a matter of fact, sulphate of iron in saturated solution does not destroy the vitality of disease germs, or the infecting power of material containing them. This salt is, nevertheless, a very valuable antiseptic, and its low price makes it one of the most available agents for the arrest of putrefactive decomposition.

Antiseptic agents, however, exercise a restraining influence upon the development of disease germs, and their use during epidemics is to be

recommended when masses of organic material in the vicinity of human habitations cannot be completely destroyed, or removed, or disinfected.

While an antiseptic agent is not necessarily a disinfectant, all disinfectants are antiseptics; for putrefactive decomposition is due to the development of "germs" of the same class as that to which disease germs belong, and the agents which destroy the latter also destroy the bacteria of putrefaction when brought in contact with them in sufficient quantity, or restrain their development when present in smaller amounts. A large number of the proprietary "disinfectants," so-called, which are in the market, are simply deodorizers or antiseptics, of greater or less value, and are entirely untrustworthy for disinfecting purposes.

Antiseptics are to be used at all times when it is impracticable to remove filth from the vicinity of human habitations, but they are a poor substitute for cleanliness. During the prevalence of epidemic diseases, such as yellow fever, typhoid fever, and cholera, it is better to use in privy-vaults, cess-pools, etc., those antiseptics which are also disinfectants, *i.e.*, germicides; and when the contents of such receptacles are known to be infected, this becomes imperative.

Still more important is the destruction at our seaport quarantine stations of infectious material which has its origin outside of the boundaries of the United States, and the destruction within our boundaries, of infectious material given off from the persons of those attacked with any infectious disease, whether imported or of indigenous origin.

In the sick-room we have disease germs at an advantage, for we know where to find them as well as how to kill them. Having this knowledge, not to apply it would be criminal negligence, for our efforts to restrict the extension of infectious diseases must depend largely upon the proper use of disinfectants in the sick-room.

GENERAL DIRECTIONS.

Disinfection of Excreta, etc. The infectious character of the dejections of patients suffering from cholera and from typhoid fever is well established; and this is true of mild cases and of the earliest stages of these diseases as well as of severe and fatal cases. It is probable that epidemic dysentery, tuberculosis, and perhaps diphtheria, yellow fever, scarlet fever, and typhus fever, may also be transmitted by means of the alvine discharges of the sick. It is therefore of the first importance that these should be disinfected. In cholera, diphtheria, yellow fever, and scarlet fever, all vomited material should also be looked upon as infectious. And in tuberculosis, diphtheria, scarlet fever, and infectious pneumonia, the sputa of the sick should be disinfected or destroyed by fire. It seems advisable also to treat the urine of patients sick with an infectious

disease with one of the disinfecting solutions below recommended.

Chloride of lime, or bleaching powder, is perhaps entitled to the first place for disinfecting excreta on account of the rapidity of its action. The following standard solution is recommended:

Dissolve chloride of lime of the best quality⁶ in pure water, in the proportion of six ounces to the gallon.

Use one quart of this solution for the disinfection of each discharge in cholera, typhoid fever, etc.⁶ Mix well, and leave in the vessel for at least one hour before throwing into privy-vault or water closet. The same directions apply for the disinfection of vomited matters. Infected sputum should be discharged directly into a cup half-full of the solution. A 5 per cent. solution of carbolic acid may be used instead of the chloride of lime solution, the time of exposure to the action of the disinfectant being four hours.

Disinfection of the person. The surface of the body of a sick person, or of his attendants, when soiled with infectious discharges, should be at once cleansed with a suitable disinfecting agent. For this purpose solution of chlorinated soda (liquor sodæ chlorinatæ) diluted with nine parts of water, or the standard solution of chloride of lime diluted with three parts of water, may be used. A 2 per cent. solution of carbolic acid is also suitable for this purpose, and under proper medical supervision the use of a solution of corrosive sublimate—1:1,000—is to be recommended.

In diseases like small-pox and scarlet fever, in which the infectious agent is given off from the entire surface of the body, occasional ablutions with the above mentioned solution of chlorinated soda are recommended.

In all infectious diseases the body of the dead should be enveloped in a sheet saturated with the standard solution of chloride of lime, or with a 5 per cent. solution of carbolic acid, or a 1:500 solution of corrosive sublimate.

Disinfection of clothing. Boiling for half an hour will destroy the vitality of all known disease germs, and there is no better way of disinfecting clothing or bedding which can be washed than to put it through the ordinary operations of the laundry. No delay should occur, however, between the time of removing soiled clothing from the person or the bed of the sick and its immersion in boiling water, or in one of the following solutions until this can be done:

Corrosive sublimate one drachm to the gallon of water (about 1:1,000), or,

Carbolic acid, pure, one ounce to the gallon of water (1:128).

⁶ Good chloride of lime should contain at least 25 per cent. of available chlorine (page 92). It may be purchased by the quantity at 3½ cents per pound. The cost of the standard solution recommended is, therefore, but little more than 1 cent a gallon. A clear solution may be obtained by filtration or by decantation, but the insoluble sediment does no harm, and this is an unnecessary refinement.

⁷ For a very copious discharge, use a large quantity.

The articles to be disinfected must be thoroughly soaked with the disinfecting solution and left in it for at least two hours, after which they may be wrung out and sent to the wash.

N. B. Solutions of corrosive sublimate should not be placed in metal receptacles, for the salt is decomposed and the mercury precipitated by contact with copper, lead, or tin. A wooden tub or earthen crock is a suitable receptacle for such solutions.

Clothing or bedding which cannot be washed should be disinfected by steam in a properly constructed disinfection chamber. In the absence of a suitable steam disinfecting apparatus, infected clothing and bedding should be burned.

Disinfection of the sick-room. In the sick-room no disinfectant can take the place of free ventilation and cleanliness. It is an axiom in sanitary science that it is impracticable to disinfect an occupied apartment for the reason that disease germs are not destroyed by the presence in the atmosphere of any known disinfectant in respirable quantity. Bad odors may be neutralized, but this does not constitute disinfection in the sense in which the term is here used. These bad odors are, for the most part, an indication of want of cleanliness, or of proper ventilation; and it is better to turn contaminated air out of the window or up the chimney than to attempt to purify it by the use of volatile chemical agents, such as carbolic acid, chlorine, etc., which are all more or less offensive to the sick, and are useless so far as disinfection—properly so called—is concerned.

When an apartment which has been occupied by a sick person with an infectious disease has been vacated, it should be disinfected. The object of disinfection in the sick-room is mainly the destruction of infectious material attached to surfaces, or deposited as dust upon window ledges, in crevices, etc. If the room has been properly cleansed and ventilated while still occupied by the sick person, and especially if it was stripped of carpets and unnecessary furniture at the outset of his attack, the difficulties of disinfection will be greatly reduced.

All surfaces should be thoroughly washed with the standard solution of chloride of lime diluted with three parts of water, or with 1:1,000 solution of corrosive sublimate. The walls and ceiling, if plastered, should be subsequently treated with a lime-wash. Especial care must be taken to wash away all dust from window ledges and other places where it may have settled, and thoroughly to cleanse crevices and out-of-the-way places. After this application of the disinfection solution, and an interval of twenty-four hours or longer for free ventilation, the floors and wood-work should be well scrubbed with soap and hot water, and this should be followed by a second more prolonged exposure to fresh air, admitted through open doors and windows.

As an additional precaution, fumigation with sulphurous acid gas is to be recommended, especially for rooms which have been occupied by patients with small-pox, scarlet fever, diphtheria, typhus fever and yellow fever. But fumigation with sulphurous acid gas alone, as commonly practiced, cannot be relied upon for disinfection of the sick-room and its contents, including bedding, furniture, infected clothing, etc., as is popularly believed.

When fumigation is practiced, it should precede the general washing with a disinfecting solution heretofore recommended. To ensure any results of value, it will be necessary to close the apartment to be disinfected as completely as possible by stopping all apertures through which the gas might escape, and to burn not less than three pounds of sulphur for each thousand cubic feet of air space in the room. To secure complete combustion of the sulphur, it should be placed in powder or in small fragments, in a shallow iron pan, which should be set on a couple of bricks in a tub partly filled with water, to guard against fire. The sulphur should be thoroughly moistened with alcohol before igniting it.

Disinfection of privy vaults, cesspools, etc. When the excreta (not previously disinfected) of patients with cholera or typhoid fever have been thrown into a privy vault, this is infected, and disinfection should be resorted to as soon as the fact is discovered, or whenever there is reasonable suspicion that such is the case. It will be advisable to take the same precautions with reference to privy vaults into which the excreta of yellow fever patients have been thrown, although we do not definitely know that this is infectious material.

For this purpose the standard solution of chloride of lime may be used in quantity proportioned to the amount of material to be disinfected, but where this is considerable it will scarcely be practicable to sterilize the whole mass. The liberal and repeated use of this solution, or of a 5 per cent. solution of carbolic acid will, however, disinfect the surface of the mass, and is especially to be recommended during the epidemic prevalence of typhoid fever or of cholera.

All exposed portions of the vault, and the wood-work above it, should be thoroughly washed down with the disinfecting solution. Instead of the disinfecting solutions recommended, chloride of lime in powder may be daily scattered over the contents of the privy vault.

Disinfection of ingesta. It is well established that cholera and typhoid fever are very frequently, and perhaps usually, transmitted through the medium of infected water or articles of food, and especially milk. Fortunately we have a simple means at hand for disinfecting such infected fluids. This consists in the application of heat. The boiling temperature maintained for half an

hour kills all known disease germs. So far as the germs of cholera, yellow fever, and diphtheria are concerned, there is good reason to believe that a temperature considerably below the boiling point of water will destroy them. But in order to keep on the safe side, it is best not to trust anything short of the boiling point (212° F.) when the object is to disinfect food or drink which is open to the suspicion of containing the germs of any infectious disease.

During the prevalence of an epidemic of cholera it is well to boil all the water for drinking purposes. After boiling, the water may be filtered, if necessary to remove sediment, and then cooled with pure ice if desired.

FOREIGN CORRESPONDENCE.

LETTER FROM LONDON.

(FROM OUR OWN CORRESPONDENT.)

Novel Treatment of Meningitis—Chemistry for Pharmacists—A University for London—The Pasteur Treatment—Nephrorrhaphy for Movable Kidney—Ichthyol in Erysipelas.

Singular superstitions prevail in Paris, despite its claim to be the centre of modern civilization. A woman, whose child was suffering from meningitis, concluded to try an old-wives' remedy, and she accordingly allowed a pigeon to be killed on the little patient's head, in belief that the malady would be absorbed by the pigeon's flowing blood. The doctor in attendance learned, to his surprise, that the practice is by no means uncommon, and that one woman in the Halles sells on a daily average ten or twelve pigeons destined for this singular sacrifice.

From the address of Sir Henry Roscoe at the opening of the forty-seventh session of the School of Pharmacy, he mentioned that for skill and cunning in the discovery and preparation of "simples," the German pharmacist leaves his English brother really nowhere. Well might the President of this inaugural gathering ask why it is that so much more is done on the Continent than in England in the preparation of rare drugs and in the discovery of new ones, of artificial febrifuges and antipyretics, to say nothing of such interesting bodies as saccharin and other products of foreign science and skill. "It is simply," says Sir Henry, "because a more ample opportunity is given to him for the study of chemistry in its higher stages and in its application to pharmacy than has hitherto been accorded to us." It is consoling, however, to be assured that the Research Laboratory of the School of Pharmacy will do something to set this matter right.

The event of the past week has been the commencement of the winter session in the medical

schools. Up to the present the entrances of fresh students have been decidedly below the average of past years. Professor John Eric Erichsen, speaking at King's College, stated that King's College and University College had coöperated in furthering one of the noblest and greatest educational works ever propounded in London, viz.: the endeavor to establish, for the first time in the history of London, a University in and for London. A Royal Commission had been sitting for some months to consider the advisability of acceding to the petition of the two Colleges for the proposed new University. There was a great deal of misapprehension in the public mind as to the proposed Albert University. The sons and daughters of Londoners suffered much from the difficulty of obtaining a thorough university education in the metropolis, and it was now necessary for them to go to distant institutions in pursuit of such an education. But both King's College and University College possessed every requisite for that system of university education. Taking their size, wealth and endowments, and their general position as educational establishments, the governing bodies of the colleges felt that they were fully justified in petitioning that University rank might be conferred upon them. If the petition were granted, and if University rank were granted to the two Colleges, in connection especially with the medical schools of London, they would be able to start at once with a body of undergraduates more numerous than that possessed by any University in the United Kingdom. It would number something like 2,000 or, if those who would come in from other medical schools were included, the number would be considerably over 3,000. The medical profession was, the Professor said in conclusion, the Republic of Medicine in this sense—that there was no hereditary road to it, and there was no privileged class in it. Every position in it was open to all men who had the ability to aspire to and the will to seize it.

Detractors of Professor Pasteur are attaching great importance to the case of a young man who has just died of hydrophobia twenty-seven months after the completion of the Pasteur treatment. The deceased, a farmer 26 years of age, was bitten by a mad dog in the month of May, 1886, in the little finger of the right hand. On the tip of the finger there were three wounds, which were in the first place canterized with a red-hot iron—this precaution, however, not being taken until two or three days after the accident. Soon afterwards the farmer came to Paris, presented himself at the Pasteur laboratory and underwent the usual course of treatment. He returned home and enjoyed his usual health until the summer of the present year, when he caught a slight cold and complained of pain in the bitten finger. The pain rapidly extended to the arm, the shoulder and the right side, and a day or two subsequently he became

convulsive and was removed to a hospital, where he died with all the usual symptoms of rabies. The conclusion M. Pasteur's adversaries draw from this case is that the eminent Professor's system offers no guarantee against the terrible consequences that may attend the bite of a mad dog. Probably, however, M. Pasteur will have something to say respecting the case referred to which will give it another aspect.

Mr. Gould has recently, at the Middlesex Hospital, successfully performed the operation of fixing a movable kidney. Mr. Gould considers the mode of passing the suture of great importance. Instead of making a large curved needle, such as is usually employed, carry the suture at a single sweep through the organ and lumbar aponeurosis, he prefers first to pass the suture through the kidney, taking up as broad a piece of its capsule and cortex as possible, and then to pass each end of the suture through its corresponding portion of the lumbar aponeurosis. Two sutures passed in this manner are found sufficient to hold the kidney firmly, and if they are tied carefully, the chance of their cutting out through the kidney, and so not holding it so securely as desired, are reduced to a minimum. A subsidiary advantage of the buried suture is that the wound can be closed smoothly and accurately by the ordinary sutures. When the kidney is fixed by external sutures they pucker the wound and interfere with the most rapid and perfect healing. As to the material of the deep sutures, Mr. Gould considers silk, as being more durable than gut or tendon, would be preferable, were it not that it is more difficult to render absolutely aseptic than is kangaroo tendon. That, at any rate, is his experience; and the tendon has answered so well in his hands as a ligature in ovariectomy and as a suture in the radical cure of hernia, that he uses it with full confidence.

Ichthyol for erysipelas has been successful in the hands of some medical men. It is used in combination with ether, 10 parts of each in 180 parts of collodion, as a local application. An ointment composed of equal parts of ichthyol and vaseline has also been successfully employed.

DOMESTIC CORRESPONDENCE.

Monstrosities and Mental Impressions.

Dear Sir:—The article in *THE JOURNAL* of October 13th reminds us that for ages woman has been tortured with fears and anxieties created by those who should be her shield and strength. Hardly a woman since Satan

"Squat like a toad close at the ear of Eve,
Assaying by his devilish arts to reach
The organs of her fancy,"

has gone through her pregnancy without experi-

encing an impression far more potent than catching a frog instead of a fish. If by any law her fears, and hopes, and desires could change the form of her unborn child, the race would long ago have been transformed to beasts and birds and creeping things. The "ring-streaked, speckled and spotted" results of Jacob's experiments on Laban's ewes would be nothing to the markings of mankind, and we might well question the wisdom of the All Wise, as well as the power of Him who ordained "each after his kind." But from the myriad impressions, powerful impressions, made upon expectant mothers, how many leave "mother's marks," and how many mother's marks conform to any given impression? What physician has not been consulted about such impressions, and who has not had cases corresponding with this? The husband of Mrs. —, in a playful mood, brought from the barn a handful of hairless young rats, and saying to his young wife, a few weeks advanced in her first pregnancy, "Here, my dear," emptied them into her extended hands. She dropped them upon the floor and shudderingly exclaimed, "My baby will look like those things." She believed in her power to impress the child. The fear tortured her through the long months of pregnancy, and when the babe was born her first question was "Does it look like a rat?" It is hardly necessary to say it did not. Or who has not had experiences like this: The child was born, and the good ladies in attendance asked "What did you see? No? Why you must have seen something." And so they strove to find the impression that caused spina bifida. Or the child is born with an anastomotic aneurism on the head, and after many questions and cross-questions about cherries and strawberries and plums the mother at last remembers that she longed for plums.

We have seen many and various "marks" and deformities, but none that conformed any more nearly to a given idea in the mother's mind than the horse's mane in Nelligan's plates on skin diseases, or Dr. Jessup's frog; and if mothers can't do better than these examples they may as well give up mental impression art.

Let us glance a moment at the logic of what might only cause a smile if it was not the source of painful anxiety in those we love. When an ovary becomes an embryonic cell it is a new life and differentiates and proliferates other cells in harmony with its individuality. Henceforward it appropriates whatever it receives, whether from the mother's blood or breast, from cow or cook, in accordance with the laws of its own organism, and the mother has no more power through a mental impression upon her blood or milk to make its development conform to a given idea than the cow or the cook. She may, through the undue exercise of the emotions, through improper diet or disease poison the food she provides, but that is

the extent of her power. When it has entered another organism it is beyond her control. She cannot by any mental impression cause a mal-development in her own body conforming to a given idea. Much less can she produce such a result in another, however closely related to her.

Are we pointed to wonderful experiences and asked to account for them? Experience and mysticism prove anything from the cures of homeopathic dynamizations and "Christian Scientists," to "mother's marks." But as with the nostrum vender, their proof lies in advertising exceptional results, and forgetting alike the great body of facts and physiological, pathological and therapeutic principles.

The head of the fetus, being its heaviest part, ordinarily lies next the vagina. Plums, cherries, etc., are usually found about the head and shoulders. If elsewhere, note if the child had not some other presentation. A slight *punch* is sufficient in early foetal life to cause an anastomotic aneurism or other *mark*.

In 1885 we waited on Mrs. —. The baby had no forehead. The top of the head was flat and covered with bony nodules. The expression of the child was idiotic, and its limbs imperfectly developed. We saw in the expression and the imperfect development sequents of an injured and undeveloped brain. We did not inquire about mental impressions but had a history of libidinous connection that produced the conviction that quite another kind of impression had caused what we saw.

We know that some malformations are considered violations of all law—a law unto themselves. If so, we cannot account for their deformities. But, can there be any effect without an efficient cause? Our profession and humanity demands that we seek such cause and strive to quiet the cruel fears of those who bear the curse "In sorrow thou shalt bring forth children."

W. L. SCHENCK, M.D.

Osage City, Kansas, Oct. 16, 1888.

MISCELLANEOUS.

AMERICAN PUBLIC HEALTH ASSOCIATION.—The Sixteenth Annual Meeting of the American Public Health Association will be held in Milwaukee, Wis., on Tuesday, Wednesday, Thursday and Friday, November 20, 21, 22, 23, 1888, at the Athenaeum Hall, commencing at 10 A. M. Reduced R. R. rates can be secured from all sections of the country on the certificate plan. Papers and reports have been announced as follows:

The President's Address.

"The History and Administration of Quarantine in Texas, 1878 to 1888."—By R. Rutherford M.D., State Health Officer of Texas.

"The Canadian System of Maritime Sanitation."—By F. Montizambert, M.D., Quarantine Officer at Grosse Isle, St. Lawrence River.

"Yellow Fever: Panics and Useless Quarantines—its

Limitation by Temperature."—By John H. Rauch, M.D., Secretary of the State Board of Health of Illinois.

"The Organization of the National Health Service."—By Henry P. Walcott, M.D., President State Board of Health of Massachusetts.

"State Boards of Health."—By Ezra M. Hunt, M.D., Secretary of State Board of Health of New Jersey.

"The Difficulties and Success of the Public Health Service in Large Cities."—By Oscar C. DeWolf, M.D., Health Commissioner of Chicago.

"Ontario Sanitary Legislation, its Strength and its Weakness."—By John Coventry, M.D., Medical Health Officer of Windsor, Ontario, Canada.

"The Destruction of Organic Matter by Fire as a Sanitary Measure—Garbage Furnaces."—By S. S. Kilvington, M.D., President of the Board of Health of Minneapolis.

"Vaccination as a Protection from the Infection of Small-Pox."—By D. W. Hand, M.D., President of the State Board of Health of Minnesota.

"Tuberculosis, its Origin, Detection, and Control."—By D. E. Salmon, D.V.M., Chief of the Bureau of Animal Industry, Washington.

"Veterinary Sanitary Work in Wisconsin, with Special Reference to Diseases Communicable to Man."—By V. T. Atkinson, D.V.M., State Veterinarian of Wisconsin.

"The Relations of Bacteriology to the Discovery and Prevention of Causes of Infectious Diseases among Men and Animals."—By Theobald Smith, M.D., of the Bacteriological Laboratory of the Bureau of Animal Industry, Washington.

"Popular and Scholastic Education in Hygiene."—By J. T. Reeve, M.D., Secretary State Board of Health of Wisconsin.

"Remarks on the Classification of Diseases."—By Henry B. Baker, M.D., Secretary of the Michigan State Board of Health.

"Meteorological Observations as Respects Disease Prevalence."—By Prof. Payne, Director of Observatory, Northfield, Minn.

"Some Personal Observations on Yellow Fever and its Habitudes as Opposed to the Fallacies and Dangers of Personal Quarantine."—By A. N. Bell, M.D., Brooklyn, N. Y.

Valuable reports have been promised from several of the committees. Arrangements have been made for the use of the stereopticon by any who desire to avail themselves of it in illustrating papers presented, as has already been announced by circular from the president's office.

WASHINGTON OBSTETRICAL AND GYNÆCOLOGICAL SOCIETY.—At the annual business meeting held October 19, 1888, the following officers were elected for the ensuing term:

Joseph Taber Johnson, M.D., President; D. Webster Prentiss, M.D., and W. W. Johnston, M.D., Vice-Presidents; George Byrd Harrison, M.D., Treasurer; Samuel S. Adams, M.D., Recording Secretary; G. Wythe Cook, M.D., Corresponding Secretary.

AMERICAN ACADEMY OF MEDICINE.—The American Academy of Medicine will hold its next annual meeting at the New York Hospital, on Tuesday and Wednesday, November 13 and 14. Papers will be read by Drs. H. I. Bowditch, of Boston; Theophilus Parvin, of Philadelphia; Leartus Connor, of Detroit; L. D. Bulkley, of New York; J. C. Wilson, of Philadelphia; E. Andrews, of Chicago; Geo. J. Fisher, of Singing, N. Y.; C. C. Bombaugh, of Baltimore; R. L. Sibbet, of Carlisle, Pa.; W. F. Waugh, of Philadelphia; and the President's Address, by Dr. F. H. Gerrish, of Portland, Maine.

Official List of Changes in the Stations and Duties of Officers Serving in the Medical Department U. S. Army, from October 20, 1888, to October 20, 1888.

Col. Charles Page, Asst. Surgeon-General, Medical Director of the Department, will proceed to and inspect the

Medical Department at Fts. Ellis, Tex.; Supply, Reno, Sill and Gibson, I. T.; Ft. Leavenworth, Kan., and the Leavenworth Military Prison, in the order named, and upon completion of this duty return to these Hdqrs. Par. 1, S. O. 127, Hdqrs. Dept. of the Missouri, Ft. Leavenworth, Kan., October 15, 1888.

Major William D. Wolverton, Surgeon, is relieved from duty at Ft. D. A. Russell, Wyo. Ter., and will report in person to the commanding officer, Ft. Douglas, U. T., for duty at that post. Par. 16, S. O. 248, Hdqrs. of the Army, A. G. O., Washington, October 24, 1888.

Major William H. Forwood, Surgeon U. S. Army, Ft. Snelling, Minn., is granted leave of absence for one month, on surgeon's certificate of disability. S. O. 100, Hdqrs. Dept. of Dak., St. Paul, Minn., October 20, 1888.

PROMOTION.

Capt. Leonard V. Loring, Asst. Surgeon, to be Surgeon, with the rank of Major, October 9, 1888, vice Meacham, deceased.

Capt. Paul R. Brown, Asst. Surgeon, is relieved from duty at Ft. Sidney, Neb., and will report in person to the commanding officer, Ft. D. A. Russell, Wyo. Ter., for duty at that post. Par. 16, S. O. 248, Hdqrs. of the Army, A. G. O., Washington, October 24, 1888.

Major John W. Williams, Surgeon, leave of absence granted in S. O. 209, October 4, 1888, is extended one month, by direction of the Secretary of War. Par. 14, S. O. 246, A. G. O., October 22, 1888.

Capt. Edward C. Carter, Asst. Surgeon, granted leave of absence for one month, by direction of the Secretary of War, to take effect on the completion of his present duties. Par. 13, S. O. 246, A. G. O., October 22, 1888.

By direction of the Secretary of War, First Lieut. William C. Borden, Asst. Surgeon, is relieved from duty at San Antonio, Tex., and will report in person to the commanding officer, Ft. Ringgold, Tex., for duty at that post. Par. 11, S. O. 247, A. G. O., Washington, October 23, 1888.

First Lieut. R. R. Ball, Asst. Surgeon U. S. Army, granted leave of absence for one month, with permission to apply for an extension of one month. Par. 3, S. O. 129, Hdqrs. Dept. of the Missouri, Ft. Leavenworth, Kan., October 18, 1888.

Official List of Changes in the Medical Corps of the U. S. Navy for the Week Ending October 27, 1888.

P. A. Surgeon Howard Smith, detached from the "Wabash" and granted six months' leave, with permission to leave the United States.

Asst. Surgeon E. W. Auzal, ordered for examination preliminary to promotion to P. A. Surgeon.

Asst. Surgeon F. W. F. Wieber, ordered for examination preliminary to promotion to P. A. Surgeon.

Asst. Surgeon E. W. Auzal, after examination, detached from Naval Academy and to Navy Yard, New York.

Asst. Surgeon J. F. Urie, detached from the "Franklin" and to Coast Survey Str. "Gedney."

Asst. Surgeon Thos. Owens, detached from Coast Survey Str. "Gedney," and to Coast Survey Str. "Blake."

Asst. Surgeon F. A. Berryhill, detached from Coast Survey Str. "Blake" and to Naval Academy.

Asst. Surgeon A. N. T. Harris, detached from Naval Hospital, Mare Island, Cal., and wait orders.

P. A. Surgeon John H. Hall, detached from the "Monongahela" and wait orders."

P. A. Surgeon M. A. Crawford, detached from the "Vandalia" and to the "Monongahela."

CORRIGENDA.

TREATMENT OF SACRO-ILIAC TUBERCULOSIS.

Dear Sir:—Will you kindly correct, in a note in your next number, the statement in my article of October 20, 1888, page 553, that Prof. Sayre's first operation-case was not previously published? I am advised that it was published in the *Medical Record*, of New York, Feb. 6, 1879.

Very sincerely,
WELLER VANHOOK,
884 W. Madison St., Chicago.

ORIGINAL ARTICLES.

THE RADICAL CURE OF VARICOCELE, ATTENDED WITH REDUNDANCY OF SCROTUM, DEMONSTRATED BY TIME.

Announced—but not read—before the Section on Surgery, at the Thirty-ninth Annual Meeting of the American Medical Association, May, 1888.

BY MORRIS H. HENRY, M.A., M.D., LL.D.,

OFFICER OF THE ROYAL ORDER OF THE SAVIOR, OF GREECE; COMMANDER OF THE IMPERIAL ORDERS OF THE MEDJIDIE AND OF L'OSMANIE, OF TURKEY; FORMERLY SURGEON-IN-CHIEF OF THE STATE EMIGRANT HOSPITALS OF NEW YORK, ETC.

The surgical treatment of varicocele has attracted the attention of many distinguished surgeons of the day—mainly, however, among those who devote more or less especial attention to diseases of the genito-urinary organs. All surgical operations are performed for the relief or cure of disease, whether it be of an acute or chronic nature, and time alone can demonstrate the true value of any special surgical procedure.

The impression still prevails, among many of what might be termed the older surgeons, that varicocele is a disease that does not often call for surgical interference, because it can be borne by many suffering from the disease—to a limited extent—with the aid of a suspensory bandage or a flexible metal ring. In conversations with a number of those entertaining or expressing these views I am led to believe that the fear of bad results, or failure in the ligation of the veins, is the source of their impressions and their aversion to any surgical interference. I believe that non-interference may, in many instances, be of greater benefit to the patient than ligation of the veins. Every surgeon knows of the uncertainty of this operation—not only of its failure to cure, but the risk of inducing atrophy of the testes, and the excitation of inflammation to the extent of danger to life. The only argument, deserving consideration, offered by those who advocate non-interference is, that in a large number of cases the disease is not a real source of physical disability, and can be borne without much discomfort with the aid of a bandage, just as a hernia can be endured with the assistance of a truss. Sir James Paget, one of the oldest and most distinguished of living surgeons, expressed these views to me in a conversation I had with him about three years ago. He re-

marked, however, that he had retired from the field of operative surgery and had become very conservative in his views; and that, except in cases of those who desired to enter or remain in the public service, army and navy, or in positions requiring physical endurance, he was averse to any surgical interference. When I suggested that surgical aid was justified to relieve the annoyances, distress, pain and mental anxieties, the only answer that he made was: "Well, only an absolute physical disability would induce me to sanction an operation looking to the obliteration of the spermatic veins. I have never performed excision of the redundant scrotum; while it is less dangerous, I shall not have an opportunity of testing its merits. As I have already said, I have retired from operative surgery."

My purpose is not to call especial attention to the physical and other disabilities induced by the presence of even slight cases of varicocele; but to advocate, to the fullest extent of my ability, the advantages of excision of the redundant scrotum over all other methods hitherto pursued for its relief and cure.

My convictions and conclusions are based on the results of a large experience, and of extraordinary opportunities of physical examinations, covering a period of more than twenty-five years. While pursuing my own clinical observations I have not been unmindful of the labors of my colleagues, nor less watchful of the result of their cases than of my own—that is, as far as opportunities have been afforded.

The honor of the first suggestion of the operation is due to Sir Astley Cooper. He published, in his classic volume on the structure and diseases of the testis, 1841, a report of five cases in which he operated, and an additional case, with some extraordinary features, submitted by his colleague, Mr. Key; who was also in favor of the operation and with a strong preference over that of ligation of the veins. There can be no doubt that the distrust of the value of ligations of the veins, amongst British surgeons, was due to the influence and teachings of the surgeons I have just mentioned. But the new operation did not meet with any great amount of favor, owing to the fear of severe hemorrhage in its performance, and the permanency of benefit as a final result.

The German surgeons paid little or no heed to it, and the French surgeons became absorbed in the gradual constriction of the veins, leading to their obliteration, suggested by the brilliant Ricord. Curling, who has been for many years, and is still to a great extent, the British Mentor in this department of surgery, has ignored the operation, but with no additional reason to sustain his objections.

My own first practical knowledge of the operation—over thirty years ago, and while yet an undergraduate—was in being accidentally asked to assist the late distinguished and erratic Edward H. Dixon, an alumnus of the College of Physicians and Surgeons, of New York, who performed the operation on a young lawyer. That operation was not a success. The failure was due to the method of operation, and the method was faulty owing to the want of proper instruments for the performance. But to Dixon must be accorded the credit of first calling attention to the operation in this country. I am fully sustained in this view by the testimony of the oldest member of the firm of Tiemann & Co., the celebrated instrument-makers; the origin of the firm antedating the period of Sir Astley Cooper's first publication on this subject. I have examined patterns of all the instruments they have made, and heard of the many embryonic efforts of others that never fulfilled a period of gestation. Dixon's instrument consisted of two curved steel bars about 4 inches in length and $\frac{1}{4}$ inch in thickness, perforated at each end for the introduction of screws to hold the bars together when embracing the tissues to be removed. It was a failure. Many attempts have been made by others, within the past few years, to revive this same instrument on account of its cheapness, and the ulterior purpose of associating their names with the operation. Their efforts and so-called "modifications"—a term of license to take unpardonable liberties with other men's inventions—have attracted little or no attention.

My first studies of the nature and best means for the relief of varicocele commenced in 1857. I first published the results of my experience and observations in 1871. I gave a detailed account of my method of operating; illustrations of my instruments; the *rationale* of the operation and the results. They are too well known to need any further recital before this Association. While my report met with unusual and not unfavorable attention, it was still urged that obliteration of the veins alone afforded a radical cure. The phantasm of dangerous hæmorrhage attending the operation was dispelled on examination of my instruments and method of operating, but the cloud of "fear of lasting benefit" still remained. Gross, Agnew, Ashurst, Barton, Lewis, Hammond, Hutchinson, Van Buren, Keyes, Bumstead, Taylor, Otis, Bangs, Weir, Bull, Abbe and McBurney have publicly attested their appreciation of my in-

struments and method. Still, further time was asked ere a verdict should be rendered in accordance with my appeal. I waited eleven years, until 1881. I then told, before the New York Academy of Medicine and the Academy of Surgery, of Philadelphia, of my experiences. In my account of fifteen cases recorded up to that time I had met with uniform success. The cases ranged between the ages of 19 and 45, and the operations aged between one and thirteen years. Is any further evidence essential to demonstrate that there is a limit to the elasticity of the scrotum; or the resiliency of the coats of the veins under favoring circumstances; or a lessening of the enlargement under a decrease of force and shortening of the column of blood of the spermatic vessels?

I have performed the operation fifty-nine times. In four instances hydrocele existed as a complication. They have all made radical cures as far as I can learn. I have made more than ordinary efforts to obtain information of the results up to this period. The time allotted to me will not permit of details of cases; I can only give general results. Surely cases operated upon ten or more years ago; showing now no more existence of former varicoceles, are a refutation of the objection to complete excision of the redundant scrotum for the permanent relief and cure of varicocele.

It is now generally performed, either with or without ligation of the veins, in most of the hospitals in this country. In most of the advanced works on surgery it has received recognition. Bumstead and Taylor not only admitted the value of my instruments but described my operation and advocated its adoption. Van Buren admitted to me the possibility of its becoming "the operation." Keyes, in the recent revised edition of their joint work, admits it, and speaks of my "clamp" as an "admirable one." Otis is decidedly in favor of it. Mr. H. Royes Bell, who contributed to the "International Encyclopædia of Surgery," describes the operation but, from want of knowledge of what has been done, is still fearful of the permanency of good results. In France, Edward Wickham has published an admirable brochure: "De la cure radicale du Varicocele par la résection du scrotum," dedicated to Guyon and Horteloup, in which he describes the results of the operation, and belief in the permanency of the results. He has changed somewhat the curve of my clamp, but accords me credit for my observations and operations, and the part I have taken in bringing the subject before the profession.

It is now before you, gentlemen of the Section of Surgery. I have endeavored, in the short time allotted to me, to give you the salient points of my impressions and knowledge obtained from clinical experience. I know that, should you adopt my suggestions, no lesser benefits will result from your operations than from mine.

581 Fifth Ave., New York.

MALARIA; AND THE CAUSATION OF PERIODIC FEVER.

Read in the Section on State Medicine, at the Thirty-ninth Annual Meeting of the American Medical Association, Cincinnati, May, 1888.

BY HENRY B. BAKER, M.D.,
OF LANSING, MICH.

Periodicity characterizes most and perhaps all physiological changes: The normal contraction and relaxation of muscles, and of protoplasm, the pulsation of the heart, the rhythmic respiratory movements, the periodical sleep during the night, action and repose are the rule, and this applies to thought and other nervous energy. Strongly-marked liberations of vital force occur only after a period of non-action has permitted the storing up of energy, which energy when once strongly and thoroughly discharged cannot immediately be followed by another similar discharge, for which time and opportunity for the accumulation of energy in dischargeable form is requisite.

A periodic fever has, in the fact of its periodicity, a very strong indication that it is necessarily related to periodic changes in the patient, or in those environments of the patient which influence physiological periodicity. Periodic fever is most frequently associated with those diurnal changes in the environment which are known to be associated with diurnal changes in human beings; rest and sleep during the night, and action during the day, are the rule; and periodic fevers usually recur daily or in multiples of days.

The tension of the blood-vessels is in great part controlled by nerves which have been called vaso-motor nerves; and although these may not be controlled by the will, impressions on sensory nerves, and movements started by volition are capable of influencing the vaso-motor nerves, and the calibre and tonicity of blood-vessels. In my opinion these facts have important relation to periodic fever, and especially to chills and fever; because, it is well known that chill and subsequent fever not infrequently follow impressions which are purely mental. A "nervous chill" thus caused has probably come under the notice of most observant medical practitioners. The chill which not infrequently follows childbirth is also well-known, but has other factors than mental or volitional impressions, because involuntary muscular contractions also have occurred.

The common phenomena of reaction from chill, if the chill is of considerable severity, include fever. In periodic fever—"fever and ague" (which term should be transposed, because the chill uniformly precedes the fever which is apparent) if the chill is accounted for, the fever seems to be explicable as the reaction from the chill, especially as the fever is comparatively ephemeral, it soon disappears, as it should do if reactionary only, and it only reappears after an-

other chill; that is to say each recurring fever has the same cause, that cause being the chill. If this view of the case is correct, what has to be accounted for, then, is the chill, and its periodical recurrence.

The time of day when the ague chill most frequently occurs, and the circumstances under which "nervous chills" occur, are facts which should aid our search for the essential conditions. I believe the ague chill is most frequent about noon, or not far from the warmest part of the day. My tables and diagrams show that there is also most intermittent fever in the warmest months of the year. It is generally conceded that there is most intermittent fever in the hot climates. High temperature of the atmosphere then, is the most important element in the causation of ague—intermittent fever. Whether the causation is direct or indirect is an interesting question. There are facts to be presented, further on in this paper, going to show that the influence of high temperature is, to some extent, indirect—through difference in the day and night temperatures. One alleged fact of this kind is that, in very malarious localities, exposure to the very high temperature on the low lands during the hottest part of the day does not cause the ague; but if one, thus exposed, remains on the low lands during the night, ague results, although the chill may not occur until the warmest part of the day. The great difference between the low lands and the high lands at night consists in the much lower temperature on the low lands.¹ The cold experienced at night is much the greatest on the lowlands. If the night exposure to cold has causative relation to ague, how is it to be explained? Why is it that the ague chill is not coincident with the chilling influence of the cool atmosphere?

Let us examine into the phenomena:

The ague chill comes at a time later than the experience of cold. The "nervous" chill comes after the experience of the mental or other constitutional disturbance. The chill after childbirth follows the strong muscular contractions. The chill following surgical operations is after the cessation of the extreme muscular and nervous tension. The general fact seems to be that so long as the stimulus continues unabated and the organism unexhausted the nervous chill does not occur; but it occurs after the unusual tension has ceased, or after the nervous system is exhausted. The disturbed and irregular nervous control of the body in ague chill would seem analagous to the twanging of a violin string, the tension of which has been lowered below its normal pitch. The vibrations are then irregular.

I submit tables and diagrams showing the rela-

¹ Experiments in Michigan, with registering thermometers, have proved that the difference is, frequently, great.

tions of intermittent fever to atmospheric temperature.

It being apparent that whether or not there is a specific cause of ague, intermittent fever is a disturbance of the nervous system, and is, directly or indirectly, controlled by atmospheric temperature, is there ready explanation of how atmospheric temperature can control intermittent fever, irrespective of a specific cause?

But first those who think that a specific micro-organism is capable of causing periodic chill and fever may be allowed to show how it is possible for such specific cause to act periodically, or to induce periodic effects, or to cause fever or chills. It is alleged to be proved by Dr. Bernardo Schiavuzzi, in Istria, Austria, that the *bacillus malarie*, described by Drs. Klebs and Tommassi Crudeli, "is found in the atmosphere of malarial places, and more abundant the higher the temperature of the atmosphere and of the ground, and that corresponding to this the intensity of the malaria rose, meanwhile in the atmosphere of places free from fever this bacillus is not found."² It is conceivable that this bacillus or some other may be inhaled, and that its products in the body may cause such an irritation or disturbance of the nervous system as we find in ague chill, and the periodical recurrence of the chill may be nearest the time of highest atmospheric temperature, because at that time the bacillus is alleged to be most abundant in the atmosphere inhaled. But this is not in accordance with the alleged fact which seems to be well attested by numerous observers, that exposure in malarious localities in the daytime is not so frequently followed by ague as exposure during the night. And, again, no one supposes that there is any bacillus or other microorganism concerned in the causation of nervous chill from mental or emotional disturbance, or of surgical chill, or of the chill following childbirth. These last-mentioned chills do not recur, but alternations of heat and cold day and night do recur, and tables of statistics which I have examined seem to prove that they are greatest in "malarious" regions, and slight in non-malarious regions, they are great in months preceding or when intermittent fever most occurs, and they are slight in months preceding or when that disease least occurs; and it would seem that in such periodical alternations of atmospheric temperature we must find sufficient cause for the production and for the periodic recurrence of ague.

HOW ATMOSPHERIC TEMPERATURE CHANGE MAY CAUSE "CHILL."

When a person is long exposed to cool night air, the abstraction of heat from the body is great, the demand for the production of heat is great.

The impress on the nervous system is strong. If one thus exposed is awake and observant, the sensations will be remembered as peculiar as well as unpleasant. If the air is not cold enough to induce immediate reaction, there is a gradually increasing nervous tension until, if the exposure is long enough, shivering occurs, that is, the normally equable nervous control of the muscular system is disturbed. If the nervous system is well-nourished, and the exposure is not extreme, the reactionary relaxation of the superficial blood-vessels, which generally occurs on the subsequent exposure to warmth, is not great, especially if the warmth is applied to the extremities of the body.

Under some circumstances, the nervous tension, due to an exposure to an atmosphere cold compared with what has recently been experienced, does not soon reach that stage where shivering occurs. Perhaps the shivering occurs soonest when the sensation of the chill is more local than general, and the most intense nervous tension without shivering is caused in those cases where the attention has been least called to the nervous disturbance, because the impress of the cold has been most gradual as well as general.³

Given, a case of intense nervous tonicities (due to impress of a cool atmosphere during the night) and consequent clonic contraction of the involuntary muscular tissue of the integument, what may occur on the experience of the day atmosphere, in warm weather? If the strong contractions on the surfaces of the body continue, and the production of heat goes on at the same rate, the heat-loss will be greatly lessened, and this will be beneficial so long as the temperature of the body remains not above the normal; but if after a time the temperature of the air inhaled becomes much warmer, the heat-loss through respiration is, consequently, much less, the internal body temperature may then become abnormally high, as is the case, I believe, in the cold stage of ague. The abnormally high internal temperature and the disturbed nervous control cause irregular muscular contractions, and the other subjective and objective phenomena of the chill; and, as is well known, these disturbances may be intensified on exposing the back of a person in this condition to the sun. The high temperature is caused (as I believe) by the continued tonicities of the muscular system of the integument, which does so much to regulate the heat-loss of the body, and which, under the circumstances I have described, has been greatly stimulated in such a *gradual* manner that immediate reaction did not occur; but when the reaction does finally occur, it is excessive and exhibits that heat of the surface which is recognized, by even non-professional persons, as "fever." The relaxation of the surfaces, brought

² Concerning Malaria in general, and particularly in Istria. Wiener Medizinische Presse, 1887, No. 52, page 1779-80.
Also letter to the author of this paper, from Prof. Conrad Tommassi Crudeli, submitted to this meeting herewith.

³ See diagram and text relative to conditions in India.

about by this reaction, then proceeds until its maximum is reached in the sweating stage.

Thus we have, according to my view, a clear grasp of the manner in which a first paroxysm of ague is caused by exposure to changes in atmospheric temperature. Given such alternations in atmospheric temperature as will cause a first paroxysm of ague, the chances are greatly in favor of there being similar alternations on the day succeeding, or, if not on that day, in a day or two afterwards, especially if it chanced to be at that season of the year when the difference between the day and night temperature tends to continue uniform; and the repetition of those conditions which caused the first paroxysm should cause a second, and a third, and so on continually so long as the cause is repeated until death, or until the nervous system, which controls the surfaces, gains such sensitiveness to those insidious changes in the atmospheric temperature that normal or appropriate reaction promptly occurs on the experience of exposure to such insidious changes.

This view explains why it is that quinine, strychnine, and those agents which have such influence on the tonicity of the muscles, voluntary and involuntary, especially those which like quinine, have strong influence on the involuntary muscular system, have such influence over ague. Strychnine, as is well-known, renders the nervous system particularly sensitive to external impressions; but its effects, in medicinal doses, are perhaps not so lasting as are those of quinine.

It is a common observation that persons who travel northward, or to a colder climate, where ague is comparatively rare, not infrequently have one or more paroxysms of chills and fever soon after the change.⁴ The common explanation is that they brought the disease with them in their systems. But this is not philosophic, because so long as they were at the South, to the temperature changes of which locality they were acclimated, they had no ague. The true explanation is that they were not acclimated to the temperature changes in the cooler region; the contractions of the surfaces, due to the tonic effects of the cooler climate, did not readily permit of the loss of any unusual body heat, such as would result from muscular exertions; the nervous centres suffered, and chill and fever resulted.

That persons not acclimated to a warm climate suffer from ague, is a still more well-known fact. It seems difficult to account for this by any other theory than the one which I am advocating; and by this theory it seems perfectly plain, because, in warm climates the daily fluctuations of temperature are so much greater than they are in temperate or cool climates; the demands upon

the heat-regulating nervous system are therefore correspondingly greater.

BLOOD CHANGES IN AGUE.

The evidence relative to the excessive formation of pigment by disintegration of the red blood-corpuses, through internal congestions and the greatly varying constitution of the blood serum as regards water and salts, because of the excessive thirst and perspiration in ague, seems to have been omitted from this paper; but this reference to it may serve to suggest that, in the opinion of the writer, the evidence is in harmony with the other portions of this paper.

DAILY RANGE OF ATMOSPHERIC TEMPERATURE DETERMINES INTERMITTENT FEVER.

From time to time I have published⁵ evidence tending to prove that the prevalence of intermittent fever throughout the world is in proportion to the difference between the day and night temperature—the average daily range of temperature to which people are exposed.⁶

With this paper I submit tables and diagrams proving, as I think, that so far as relates to certain parts of the world, this general law is correct. It is true in Michigan. It is true of that part of this country occupied by the U. S. Armies during the late war of 1861-5. The tables and diagrams sustaining this last statement include a study of the months of occurrence of over half a million cases (542,009) of intermittent fever, a number so vast that even though only three years' time is covered there is extremely great probability that true averages have been reached. If you will study the diagram (No. 1.) you will see that the curve representing the cases of intermittent fever follows with great uniformity the curve for average daily range of atmospheric temperature. It follows it in such a manner as to demonstrate, I think, that there is a necessary relation; and taken in connection with what we know of the regulation of body temperature by nerves which are in necessary relation to, and which normally respond to changes in the atmospheric temperature, the diagram seems to demonstrate a relation of cause and effect between daily range of temperature and intermittent fever.

By the diagram it will be seen that so long as the daily range is increasing the number of cases under observation accumulate, perhaps because

⁵ Reports of Michigan State Board of Health, especially for that of 1880, p. 318.

⁶ "It may be well to bear in mind in relation to this subject that intermittent fever is a disease of the warm season in this State, that it becomes more and more prevalent as we go south until in the extreme Southern States it is extremely common and severe, that the daily range of temperature is greatest in the warm months in this State, that it is greater in the warmer climates of the Southern States, that this is especially true on the lowlands, and that it is exposure during the day and during the night on the lowlands in the South which is believed to be so uniformly productive of chills and fever.

"If periodic chills and fever is produced or greatly favored by excessive periodic changes in the temperature of the atmosphere, then the reason is supplied why exposure on the hot lowlands during the day and return to the warm highlands at night is not so productive of ague as is exposure to the cold night-air of the lowlands." Page 318, Rep. Mich State Board of Health, 1880.

⁴ During the late war, I noticed this on a large scale after movements of troops from the South.

¹ More complete headings, and details of the extent and sources of the facts included in these Tables, are given in the diagrams, Nos. 1 to 12, which graphically exhibit the facts which are numerically stated in these Tables.

those made sick are kept sick by still more unfavorable temperature ranges; to such an extent is this true that the greatest effect of the unfavorable range seems to extend to the month following the change in atmospheric temperature range. But, on the other hand, when the change in the range of atmospheric temperature is in the opposite direction—toward lessened range—a condition favorable to freedom from intermittent fever, then, at least after the first such month, the fever falls nearly with the decrease in the range; probably because under the atmospheric condition which does not tend to

cause the chills and fever, those who contracted the disease under the less favorable conditions tend rapidly to recover under the more favorable condition, so there is little or no accumulation of cases.

The evidence in the table and diagram relating to the intermittent fever in the U. S. Armies during the late war I consider very powerful, representing as they do so many cases among persons more than usually exposed to out-door conditions. Then, too, the statistics are of cases of sickness which must be considered to have a close relation

to causative conditions, perhaps closer than would be the deaths.

RANGE OF TEMPERATURE SOMETIMES HAS
DIRECT, SOMETIMES INDIRECT RELATION
TO INTERMITTENT FEVER.

Although there is demonstrated to be a direct close relation between the daily range of atmospheric temperature and intermittent fever in Michigan, and in that part of this country in which the U. S. Armies were during the years 1862, 3 and 4, a study of the subject in other parts of this country and in other countries where the average daily range of atmospheric temperature is either greater or less than it is in Michigan, seems to prove that in such parts of the world the relationship is reversed.

The strongest evidence on this part of the subject that I have found is that shown in the tables and diagrams relating to range of temperature and sickness from intermittent fever in the European and native troops in the armies in India, (Diagrams Nos. 10 and 11) representing, respectively, 20,268 and 41,232 cases of intermittent fever which occurred during a single year, 1886. In the diagram (No. 10) relating to the European troops, the curve representing the range of temperature is drawn as if the relation were direct, but it is evident that it is not direct, yet that it sustained a well-marked relationship, inversely. [The diagram has been re-drawn, reversing the curve for range of temperature.]

That it is not the average *temperature* alone that controls the fever is shown by the fact that in many of the diagrams the curve for the fever has variations for which there are no corresponding variations in the curve for temperature; but there are variations somewhat similar, although sometimes reversed, in the curve representing the *range* of temperature.

In the diagram (No. 11) relating to the native troops, the curve for *range* of temperature is drawn so that the scale increases downwards, and the diagram shows somewhat close inverse relationship between the range of temperature and the intermittent fever. In this diagram, also, there are variations in the curve representing fever which are not accounted for by the curve for *temperature*, and are better accounted for by reference to the curve for *range* of temperature. That in both European and native troops the fever continued to prevail until November, notwithstanding the changes in both temperature and range of temperature had occurred three to five months earlier, may possibly be accounted for by the accumulation of cases, in connection with the fact that the temperature had commenced its downward movement so that there was increasing exposure to temperatures comparatively low.

HOW DO THE EVIDENCES HARMONIZE ?

Taking the evidence as it stands it is strong to

the effect that in Michigan and the U. S. Armies the intermittent fever is quantitatively related to the daily range of atmospheric temperature, the *greater* the range the more intermittent fever; and that in India the fever is quantitatively related to the daily range of temperature, the *less* the range the more intermittent fever. I believe there is evidence of a similar reversal of relationship in some parts of this country, where the average daily range of temperature is very great or very little; although the statistics for such places do not cover a very great number of cases of sickness.

In another part of this paper there is an attempt to learn the conditions which tend most strongly toward the production of such a clonic spasm of the contractile fibres in the integument that loss of body heat is prevented, and the spasm or contraction does not yield until after a higher than normal internal body temperature has resulted. In that part of this paper, the conclusion is reached that the impress which most certainly tends to produce this condition of the body is the very insidious yet considerable cooling of the surface of the body generally; that sudden great changes in temperature (such as occurs in winter when one goes from a warm room directly into an atmosphere at the temperature of zero), are generally reacted against at once, and are not only recognized by the senses, but are unconsciously guarded against, and especially attract attention if confined to a particular small portion of the body. One method of resuscitating persons lacking in nervous control is to submit them to rapid changes in temperature by the alternate application of hot and cold water, or by other similar means to bring about immediate reaction.⁷

In physics, I believe the law is that "action and reaction are equal and opposite;" but whether or not the motion resulting from an action shall continue in the same direction, or be reversed in direction, depends upon the amount of resistance to its continuance, and upon the suddenness of the impact. An insidious change in atmospheric temperature which cools and constricts the surface of the body does not, so often as does a sudden change, meet with that resistance or proper response by the nervous system which is requisite in order that the normal regulation of the body temperature shall be brought about immediately.

If the proper reaction to cold is immediate it is useful; but when the reaction comes only after the conditions have so far changed that, instead of there being cold to react against, heat is being applied, then the result is a body temperature abnormally high, in which case, so long as the sur-

⁷ In the experience of sudden changes, the system has an impress analogous to that given the billiard ball, struck by the cue, when a "draw" ball is played; while in the experience of the insidious change the system has an impress analogous to that given the ball when a "follow" ball is played, in which case the impress continues after the ball has struck another, in spite of the opposing force which, under the condition first named, served to reverse the direction of the motion.

face of the body is cool and purple, we may have those sensations and appearances which are called chill; but as soon as the reaction is established, there is that higher than normal external as well as internal body temperature which has long been known as fever.

If we have reached the correct explanation of the mechanism of intermittent fever, we have explained why it is that in those parts of the world where the daily changes of atmospheric temperature are usually *very great*, the body is acclimated to and is best able to react against those changes which are most pronounced, and least likely to react against those changes which are most insidious. In India, then, and at Fort Apache, Arizona Ter., where the average daily range of atmospheric temperature is excessive, the intermittent fever should be inversely proportional to the average daily range of atmospheric temperature. These statistics seem to prove that this is so.

On the other hand, in those parts of the world where a majority of the daily changes in temperature are comparatively insidious, but where the inhabitants are so "toned up" that intermittent fever is not so often experienced, the greater the extent of the daily change in atmospheric temperature the greater the chance of causing intermittent fever, through unusual demands upon the heat-regulating nerves. In Michigan and those other temperate parts of the United States where those conditions prevail, the intermittent fever should be directly and quantitatively proportional to the average daily range of the atmospheric temperature. These statistics seem to prove that this is so.

In a few of the tables and diagrams which I have studied, there seems to be evidence that where the average daily range of atmospheric temperature is excessively small, the effect on the fever is uncertain.

In a few of the tables and diagrams there seems to be shown a direct relationship of range of atmospheric temperature to intermittent fever in all the months in which the average range is below about 16°, while in months when the range is above that, the relationship seems to be reversed; but even in such cases there is apparently good evidence that range of atmospheric temperature has influence.

In nearly all the instances studied, it is apparent that intermittent fever is more closely related to daily *range* of temperature than to the *average* temperature. It follows, therefore, that if the bacteria in the atmosphere alleged to cause the fever increase, as stated by Dr. B. Schiavuzzi, in proportion to the temperature of the *atmosphere*, then the experience of range of atmospheric temperature is a stronger controlling factor than is the bacillus malarie in the causation of intermittent fever.

If, however, the bacillus malarie is capable of

causing the fever, and it is in the atmosphere in proportion to the temperature of the *earth* (as also is alleged by Dr. Schiavuzzi), then we must await further evidence, because we have not yet sufficient statistics of the proportional prevalence of the bacillus in each month of the year at a sufficient number of parts of the world, nor sufficient collected and tabulated data of the temperature of the earth in different parts of the world, to answer the question.

SUMMARY.

So far as evidence is yet presented, it seems to be proved, then, that:

1. Intermittent fever is proportional, directly or inversely, to the average daily *range* of atmospheric temperature.

2. The *controlling* cause of intermittent fever is exposure to insidious changes, or changes to which one is unaccustomed, in the atmospheric temperature.

3. In the mechanism of the causation of intermittent fever, the chief factor is the delay in the reaction from exposure to cool air; this delay, extending to a time when greater heat-loss should occur, results in the abnormal accumulation of heat in the interior of the body, and in disturbed nervous action—the chill; and the final reaction is excessive, because of the accumulation of heat and, sometimes, because it occurs at the warmest part of the day.

4. The fever is the excessive reaction from the insidious influence of the exposure to cool air; and it is periodical because of the periodicity of nervous action, and because the *exposure* and the consequent chill are periodical, owing to the nightly absence of the warmth from the sun.

5. Residence in valleys or on low lands through which or upon which cold air flows at night and thus causes insidious changes in the atmospheric temperature, favors intermittent fever.

6. *In our climate*, those measures, such as drainage, which enable the soil to retain warmth during the night, and thus reduce the daily range of temperature immediately over such soil, tend to decrease intermittent fever among residents thereon.

7. In the cure and prophylaxis of intermittent fever, those remedies are useful which lessen torpidity and tend to increase the power of the body to react promptly to insidious changes in atmospheric temperature.

8. The slowness of the pulse, and other indications of torpidity, associated with retention of bile or with certain disturbances of the functions of the liver, are well known; but, so far as known to the writer, these conditions have not heretofore been considered as causative of the fever in the manner herein suggested.

DISCUSSION ON DR. BAKER'S PAPER.

DR. H. A. JOHNSON, of Chicago: While it is true that the existence of parasites in the blood of

malarial patients is demonstrable, is it a justifiable inference that they cause the disease? The existence of cottonwood trees along our prairie streams do not cause the presence of the water. One of the strongest objections to the so-called hematozoon of malaria being the cause of the disease is that they cannot be cultivated. They exist in the blood plasma, principally in the corpuscles. Can it be demonstrated, 1st, that it is a heterologous form; 2d, that it is not found in any other disease than malaria. These organisms are polymorphous, amœboid. Now one of the results of the malarial form of fever is the multiplication of the white blood corpuscles. Are not these hematozoa a genesis of white blood corpuscles?

DR. W. L. SCHENCK, of Kansas: The widespread presence of periodical fevers, and especially of the so-called malarial diseases, makes the study of the various forms a matter of great importance. In old times malaria was supposed to be the potent cause of the disease. What was malaria? It escaped the microscopist and the chemist. But now it is thought we have found the cause in a bacillus. Dr. Baker's paper showed that there are other causes to be considered. I would refer to papers of my own, published by the State Medical Society, which while not elaborated as Dr. Baker's, go to support this atmospheric theory. We do not think that the frogs and mosquitoes which occur in malarial localities cause the fever, therefore why believe bacteria or hematozoa, which alike have their habitat in swampy regions, are the cause of remittent fevers. Where heat and cold cause engorgement of the organs we find the disease occurs. If all exposed wore proper clothing, protecting them against the chill of the night, the disease might be less prevalent. Heat associated with moisture enervates, and alternating cold produces central action and congestion of organs, thus causing malarial fever.

I had an example in my family. My children, during a warm summer, slept in a door-way, a draught blowing over them. In five days they had malarial fever, yet no other member of the family nor no one in the neighborhood was so affected.

I believe the efficacy of quinia in this disease is its influence in producing disgorgement of the central organs, and stimulating their tonicity prevents reëngorgement.

DR. SHARP, of Mo.: I think the physical and chemical forces have been canvassed as far back as the time of Daniel Drake. He considered it was caused by an animalcule, not from microscopical study, but from the study of the disease. Nothing but a living organism will elaborate chemical compounds. Our bodies are only destroyed by living organisms. I am not yet prepared to accept the doctrine of living organisms as the cause of disease. Living in a malarial re-

gion, it soon becomes apparent to one that exposure in the early morning or evening causes the fever. From this experience alone strong support may be given to the theory advanced by Dr. Baker.

DR. LEE, of Pa.: I think Dr. Baker's paper the strongest and most ingenious argument in favor of a theory which has always seemed to me weak and inconclusive, that I have ever heard. The whole aspect of a malarial chill is that of an organism striving under a living poison. First, the powerful contraction of the blood-vessels under the influence of the vaso-motor system, causing the chill, indicates the presence of the poison and the impression it is making on the nervous system. Second, the febrile rise indicates the reaction from the poison. Third, there is the elimination from the emunctories of the noxious or effete material. The theory of heat and cold is quite inadequate to account for the periodicity of malarial fever. Cholera is similar in its phenomena, but the system does not always react as quickly from the stage of depression, hence the fatal issue. In our Western States we have a condition analogous to cholera in the congestive chill.

If heat and cold are the causes of ague we should have quotidian chill. Yet we know the latter are not the most frequent form; there is nearly always an interval making the chill tertian or quartan. It does not yet seem clearly proved how heat and cold cause malaria.

If we suppose the presence in the blood of an organism which has a certain life history and arrives at maturity in a certain number of hours we may have a rational explanation of the cause and effect of malaria.

Changes of heat and cold, we know, are as frequent in winter as in summer, therefore—if this theory were true—we ought to have the disease prevalent in winter as well as in summer.

MULLEIN IN THE TREATMENT OF MALARIAL TROUBLES.

Read in the Section on Practical Medicine, at the Thirty-ninth Annual Meeting of the American Medical Association, May, 1888.

BY GEORGE BYRD HARRISON, M.D.,
OF WASHINGTON, D. C.

This brief paper is intended to draw attention to the remarkable results obtained, in certain sections of the South, during the war between the States, in the treatment of malarial fevers, by means of a very common and homely plant, mullein; (*verbascum thapsus* of Linnaeus). Perhaps it is wrong to speak of it as a "homely" plant, because it seems that all of its family seen in this country, (some three varieties), have been imported from Europe. "Familiar," would give

a better description. Although not an adult, during the earlier years of the revolution, I was old enough to note the signal effects of this herb as used in the treatment of malarial troubles. Quinine amongst us in those days was a luxury which few could command. My temporary home was upon the Upper James River, in Virginia, in a neighborhood in which chill and fever was anything but a rarity. Mullein was the resource under these circumstances, and proved to be by no means "a broken reed." I will try and give evidence of this, by direct testimony other than my own, later in my paper: regretting that, (owing to the state of things, then existing), it is not medical testimony, strictly speaking. I have selected this subject because our dispensaries, while placing *verbascum* quite conspicuously in their secondary list, and according to it a catalogue of virtues, are singularly silent as to its antimalarial properties. Wood, Bartholow, and Lauder Brunton ignore the vegetable, altogether, in their treatises upon *Materia Medica*.

Francis Peyre Porcher, in his well-known work, "Resources of the Southern Fields and Forests," says (Edition, 1869), "Of the order *scrofulariaceæ* (*fig-wort-tribe*), generally acrid and bitterish, sometimes dangerous in their properties; is mullein, (*verbascum thapsus-walt*) diffused; grows in pastures upper and lower districts, flowers in July" (a number of references given here); "The leaves of the flowers contain a narcotic principle. A decoction of the flowers and leaves (as tea), is beneficial in dysentery and tenesmus; it calms pain in the fundament, caused by hæmorrhoids; and it is used in the convulsions of infants; in ardor *uriæ*, and wherever the indication is to moderate spasm or irritation. A large quantity of the flowers will even induce sleep, so active is the narcotic principle it contains." (References given). This distinguished author then, after enumerating a number of diseases in which the plant is useful, and ascribing its value to "anodyne, emollient and gently astringent qualities," alludes to its employment in taking fish (the seeds being fed to them). I will not weary you by referring to a number of other complaints, in which he states that mullein has been found useful, but pass on to the following passage: "Equal parts of mullein leaves and the bark of the root of *sassafras*, boiled in water and concentrated, then mixed with powdered *sassafras* bark to form pills, are reputed valuable in the treatment of agues by herbalists." (See *Indian Guide to Health*). Surgeon Hinckley has reported several cases, in which the paroxysms of intermittent fever were completely prevented by the administration of the warm infusion of the fresh root; (4 ounces of the fresh root to one pint of water, reduced one-half by boiling; of which 2 ounces were given every hour, commencing four hours previous to the ex-

pected chill). (*Confederate S. Med. Journal*, January, 1864)."

My own recollection, of the efficacy of this herb, so strongly corroborates the observations of Surgeon Hinckley that I am entirely unwilling to resign it to the "herbalists." Within a few days past I have written to a lady (the wife of a Confederate officer of rank), whose practice, with mullein, was notably successful in my neighborhood, to ask her experience; and that she would give me her recipe. Her reply was prompt, and I give it to you at length:

R.—"Beat mullein leaves in an iron mortar; strain; and to the juice add an equal quantity of French brandy; in a wine-glass of this mixture put fifteen drops of spirits of camphor, and give just as the chill is coming on. The patient must be warmly covered and in bed before taking, and continue so for several hours after. Now for my experience: When I was told of it my husband had been having chills for seven years. I mean he had never been free from them more than a week or two at a time during that period. He would not consent to try this remedy, until one day, after taking 40 grains of quinine, he had a chill, which was so severe that we both feared congestion, and he said he would try anything. So after the chill had reached its height, I had the leaves gathered and beaten and gave him a dose. As soon as he swallowed it the moisture began to break out on his brow; and in five or ten minutes he was in a most profuse perspiration. He had not the least fever, and did not have another chill for fifteen years. I tried it after that, in, I suppose, fifty cases, *with perfect success*. Our physician in the neighborhood, (Dr. R. K. T.) used to laugh at me about it very much; but the last time I saw him he told me that during the war, when he could not get quinine, he had to resort to it, and found it most efficacious, not only in cases of chills, but in bilious and typhoid fevers. Of course he could not get brandy at that time, but used whisky instead, and usually, the commonest kind. I am glad to hear you are going to sing the praises of this wonderful plant."

I know very well that the carping reader or listener, as the case may be, will object to my adducing lay evidence of this sort, in a paper relating to a scientific subject. I know, too, that he will consider that the case notes detailed savor of inaccuracy and enthusiasm. Such a one, however, is ignorant of the peculiar state of things existing in the South, during the days of Slavery. In regard to the first proposition, he will have to be informed of the especial relations occupied by the cultivated wife of the large Southern planter to her husband's slaves ("servants" as we were taught to call them). This information, happily, I can give from the pen of a distinguished foreigner, the Marquis de Chastellux, a general officer under the Comte de

Rochambeau, in the Revolutionary War. This accomplished gentleman, after the surrender at Yorktown, made a tour of the Union and Canada; and the edition of his delightful work (from which I quote) was published in 1827, by White, Gallagher & White, No. 7 Wall Street, New York. On page 282, after describing the beauties of Westover, the old homestead of the Byrd family, on the James River, (well-known in our day as a part of McClellan's entrenched Camp), and after numerous tributes to the elegance and hospitality of his hostess, Mrs. Byrd, he says: "This lady takes great care of her negroes; makes them as happy as their situation will admit, and serves them herself as a doctor in time of sickness. She has even herself made some interesting discoveries in the disorders incident to them, and discovered a very salutary method of treating a sort of putrid fever which carries them off commonly in a few days, and against which the physicians of the country have exerted themselves without success." In reference to the case detailed, in the letter quoted, in which chronic malaria was gotten rid of by one treatment, astonishing as the result was, I can testify to a similar instance in my father's household, in which quinine had failed, and a successful result was obtained by the use of this lady's mullein-juice preparation.

Undoubtedly our Pharmacopœia is already over freighted with drugs and remedies, many of them inert or unnecessary. But in calling attention to this one, I am not introducing a new title. The plant is already "on the list." No one has greater faith than I in the virtues of cinchona and the salts of its alkaloids, especially quinine and cinchonidia, but, unfortunately, we are now and then compelled to refrain from their use by reason of personal idiosyncrasy. One man is known to me, in whom such alarming hæmaturia occurs after one dose of quinine that he cannot be induced to take it. I have known this symptom to follow a dose clandestinely given by his physician, who doubted the alleged effect. We are all accustomed to see troublesome rashes resulting from quinine and other agents of its series, as well as nervous phenomena, in some patients, which positively inhibit their employment. In the case of a very prominent gentleman, who recently died in this city and who suffered from congestive malaria, his physician gave quinine, perfectly assured from previous knowledge of the idiosyncrasy of his patient, that the nails would be shed. He told me that the result was as anticipated, nails dropping out, and skin desquamating. Arsenic stands us in good stead as a substitute in chronic cases; and Warburg's tincture is popular, with some practitioners, in acute cases. Gelsemium and other resorts we undoubtedly have; but I am sure that an antiperiodic possessing the value which I am confident pertains to this drug, would be gladly welcomed by one and

all of us—and I should feel much gratified if our enterprising manufacturing pharmacists should be led to develop its active principles, so as to offer us a convenient form of administration.

1345 F St., N. W.

A CASE OF TRANSVERSE LACERATION OF THE CERVIX UTERI.

*Read before the Medical Society of the District of Columbia,
May 16, 1888.*

BY THOMAS C. SMITH, M.D.,

OF WASHINGTON, D. C.

On May 2, 1888, I was called to see Mrs. R., colored, 23 years of age, who was seven and a half months advanced in her first pregnancy. Early in the morning she was startled by a sudden gush of fluid from the vagina, and up to the time of my visit there had been an uninterrupted discharge unattended by pain. On making an examination, the os was found undilated, but a watery fluid was passing in small quantities. No signs of labor were manifest at the time, and the patient was directed to remain in bed.

Two days later, May 4, I received another message, and saw the woman about the middle of the day. The nurse informed me that pains came on shortly after my previous visit, and that they had steadily increased in severity, but finding that no progress was being made, she had sent for me. The woman was now having almost continuous expulsive pains, and on making an examination my finger came against the os. This was undilated, and at first I thought my finger was pressing against the anus of the child; in other words, that there was a breech presentation to deal with. But on removing my finger for a moment, and again passing it up to the uterus, I was surprised to find the vertex presenting and the supposed os dilated to a diameter of some two inches. As this apparent change had taken place in less than a minute, I proceeded to make a careful examination, and the following situation was disclosed: The natural os was discovered to be nudilated so that I could scarcely pass my finger through it, while the head of the child was found to be engaged in an abnormal opening, which investigation proved to be a tear in the cervix about an inch and a half from the margin of the normal os. This laceration extended laterally about one-third of the circumference of the cervix at the point indicated, and was situated to the left and posteriorly. When the uterus contracted, the head engaged in this opening, while the normal os was absolutely unaffected by the pains.

So interesting a complication in labor induced me to invite a professional brother to make an examination, and finding Dr. J. T. Winter in the neighborhood, he was asked to see the case. After explaining the state of affairs to Dr. W., he examined the patient and satisfied himself that my

explanation was correct. As it was impossible to effect dilatation of the normal os in the presence of the laceration, and as the latter was extending, with the probability that the whole circumference of the cervix would be involved if the direction of the tear did not, indeed, change and involve the body of the uterus, I passed a probe-pointed bistoury through the laceration and out of the os, and divided the tissues so as to convert the lesion into a longitudinal laceration of the cervix. The patient experienced no pain from this procedure, which was unattended by hæmorrhage. Being apprehensive that instrumental interference might be demanded, I went to my office for my forceps, and on returning found that the child had just been born. This was separated, and the placenta delivered without trouble. The only after-treatment consisted in washing out the vagina twice daily with water which had been boiled. The woman has not had an unpleasant symptom since her delivery. A few days ago I made an examination and was hardly able to find the laceration, so well had the work of repair progressed.

Referring to lacerations of the cervix during labor, Lusk makes the following observations:

"Most commonly these lacerations follow a longitudinal direction. In rare cases, where there is extreme rigidity of the os externum, or where, after the escape of the amniotic fluid, the head distends the anterior lip without pressing upon the os, a transverse rent may occur through which the child may pass. Sometimes a longitudinal tear may be combined with one running transversely, the lip then hanging by a pedicle to the uterus, or the entire lip may be torn off. Isolated cases of so-called annular lacerations have been reported, where the transverse rent has extended through the whole vaginal portion, so that the lower segment has been detached in the form of a ring."

The foregoing quotation covers the ground admirably. In my case the os was not rigid, but failed to dilate because the uterine forces were misdirected, while the head distended the posterior lip "without pressing upon the os."

Reference to the figure will further elucidate the nature of the lesion present in the case above reported.

MEDICAL PROGRESS.

SALOL IN LUMBAR ABDOMINAL NEURALGIA.

—In gouty subjects lumbar abdominal neuralgia has a considerable importance in uterine affections, and frequently persists even after the latter disease has been cured: this is especially the case in gouty subjects, and M. J. CHERON (*Rev. Méd.-Chir. des Maladies des Femmes*, July 25, 1888) recommends in such cases the employment of salol, taken internally. This remedy, according to the author, is well supported by the stomach, and exerts a favorable action on the rheumatic and neuralgic pains. He advises that the salol should be powdered, and 10 grains divided into twenty capsules, of which two to four should be taken daily before meals. In addition to this, an ointment of salol and vaseline in equal parts may be rubbed into the lumbar sacral regions.—*Therapeutic Gazette*, Oct. 15, 1888.

MENTHOL IN PRURITUS LABII.—ALEXANDER DUKE, having seen some time since in the *Journal* an interesting paragraph by Dr. Ronth, Jr., on the value of peppermint water in cases of pruritus, I gave it a trial; but finding it only gave slight relief, I applied the crystalized menthol as sold by Shirley and others, for relieving neuralgic pain. The application produces some burning pain at first, but is followed by a most comfortable sense of coolness and relief, which relief I find lasts for days in some cases, and the congested color of the vulva almost altogether disappears. The menthol is applied by rubbing the surface over three or four times with the solid menthol, and I can certainly testify as to its value.—*Brit. Medical Journal*, Sept. 1, 1888.

HELLEBOREUS VIRIDIS IN CARDIAC DISEASES.

—DR. CHRISTOVITCH has made a series of experiments on dogs and frogs, and has used the extract of this plant in eleven cases of heart disease. He concludes that: 1. The action of the heart is increased by it, and the fulness of the pulse augmented. 2. Morbid activity of the heart is diminished in cases of excessive cardiac action. 3. Congestions of the lungs, liver and kidneys are relieved by it. 4. The secretion of urine is increased. Christovitch uses a soluble extract.—*L'Union Méd.*, Aug. 14, 1888.

TREATMENT OF INFANTILE CONVULSIONS.—A. VEILLARD recommends the following mixture for the treatment of infantile convulsions: Tincture of musk, tincture of castorium, sulphuric ether, each 32 minims; paregoric, 8 minims. Six drops are given each hour in a teaspoonful of sugared water or a teaspoonful of milk. The intervals may be lengthened as the symptoms become moderated.—*Journal de Médecine de Paris*, August 12, 1888.

Address

JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION,
No. 65 RANDOLPH STREET,
CHICAGO, ILLINOIS.

All members of the Association should send their Annual *Dues* to the *Treasurer*, Richard J. Dunglison, M.D., Lock Box 1274, Philadelphia, Pa.

LONDON OFFICE, 57 AND 59 LUDGATE HILL.

SATURDAY, NOVEMBER 10, 1888.

AN IMPORTANT AMENDMENT TO THE CONSTITUTION OF THE ASSOCIATION.

Every thoughtful member of the American Medical Association must admit that the selection of Officers and Standing Committees, and especially of the place and time of the Annual Meetings, is a duty of great importance; and should be performed in such a manner as to secure the exercise of intelligence and deliberation. And all know that hitherto this important work has been done by the Committee on Nominations, composed of one member from each State and Territory, and from the Medical Corps of the Army, Navy, and Marine Hospital Service, all selected by the members in attendance from each State, Territory, etc., during the first twenty-four hours of the Annual Meeting, and announced by the permanent Secretary on the morning of the second day. The Committee thus selected and announced almost immediately enters upon the discharge of its important duties, and is expected to make judicious nominations for the Officers, Standing Committees, Judicial Council, Trustees for Publication of THE JOURNAL, and to recommend the place and time for holding the next Annual Meeting in a few hours, and then be discharged. No member of the Committee could know that he would be called upon to act in that capacity long enough before going into the Committee room, to enable him to examine the past records of the Association, or even its Constitution and By-laws, much less to make proper inquiries concerning the place and time that

would be most advantageous for the Association and the profession to hold its next Annual Meeting. The constant liability to make mistakes and injudicious recommendations by such a Committee has been demonstrated many times during the progress of the Association, and at no time more strikingly than at the recent annual meeting in Cincinnati. The *personnel* of the Nominating Committee selected at that meeting was equal in intelligence and business tact to that of any of the committees appointed at previous meetings, and yet it recommended for local Assistant Secretary one who, at the time, was not a member of the Association, and a *time* for the holding the next annual meeting one month before there would be any adequate hotel accommodations open for the reception of members in the city selected for the *place* of meeting, and the Association adopted the recommendations. Had the Nominating Committee been a continuous business committee, one-half of whose members were selected annually, and their work so arranged that the members who were to make the nominations and recommendations at any given annual meeting would have all the preceding year in which to make necessary inquiries and make themselves familiar with the true interests of the Association, such blunders would be wellnigh impossible. It was solely for the purpose of avoiding the evils of having the most important business interests of the Association conducted in such haste, that an able committee, after much deliberation, recommended at the meeting in 1887 the following amendment to Section V of the Constitution:

The General Committee or Council shall be composed of *two members* from each State and Territorial Medical Society entitled to representation by delegates in the Association, and from the Medical Departments of the U. S. Army, Navy, and Marine Hospital Service. They shall be chosen by the members registered and present at each annual meeting, from each State, Territory, and from the Medical Corps of the U. S. Army, Navy, and Marine Hospital Service, acting separately, on the third day of each annual meeting; each delegation reporting the names of the members chosen to the Permanent Secretary of the Association on the same day, that they may be announced by him at the opening of the morning session of the fourth day. At the first election each delegation shall choose *two members* of the General Committee, one of whom shall serve *one year* and the other *two years*, and at each annual election thereafter one member shall be

chosen to serve for two years, thus making the term of office of members of the General Committee *two* years. It shall be the duty of the General Committee, thus constituted, to organize by choosing annually a Chairman and Secretary, and such sub-committees as may be found necessary to facilitate the work that may be assigned to it; to meet annually at the place and on the day preceding each annual meeting of this Association, and as often during that week as may be necessary; to nominate, on the third day of each annual meeting, all the general officers of the Association (none of whom shall be members of its own body), the members of the Committee of Arrangements, the Committee on Necrology, seven members of the Judicial Council, and three members of the Board of Trustees for Publication for election by the Association; to recommend the place and time of holding the next annual meeting; and to consider and report upon all subjects that may be referred to it by vote of the Association. The presence of one-third of the whole number of members elected to the General Committee shall constitute a quorum for the transaction of business. If, at any annual meeting of the Association, it shall be found at the close of the general meeting of the first day that a quorum of the General Committee is not present, it shall be the duty of the President and Permanent Secretary to fill the vacancies in the Committee temporarily by selections from the lists of delegates registered as present from the States to which the vacancies belong.

Should this provision be adopted by the Association, the Permanent Secretary should be authorized to substitute the name "General Committee" for "*Nominating Committee*" wherever the latter occurs in other parts of the Constitution and By-laws.

When this amendment was submitted to the meeting in 1887 in connection with the full report of the Committee, it was approved by a nearly unanimous vote of the Association. But it could not become a part of the Constitution without lying on the table and receiving the sanction of the next annual meeting. When it was taken up at the next meeting several members opposed it on the erroneous assumption that its adoption would result in taking the business out of the Association and committing it to a Council, somewhat after the manner of the British Association. As there were not enough copies of the amendment present to put one into the hands of each member to examine for himself, its further consideration was postponed until the next annual meeting. If members will now examine it carefully, they will see that by it the proposed Business Committee is

appointed by the same process as the former Nominating Committee, and that it has no power to take any business out of the hands of the Association, but simply substitutes a continuous committee so arranged as to enable it to do the work assigned to it deliberately and intelligently, instead of hastily and often imperfectly.

PUERPERAL FEVER A PREVENTABLE DISEASE.

At the opening of the 1888-89 session of the St. Thomas's Hospital, London, DR. CHARLES J. CULLINGWORTH, the obstetric physician to the Hospital, delivered an address on "Puerperal Fever a Preventable Disease," a plea for the more general adoption of antiseptics in midwifery practice. The address deals to some extent with statistics, and though short, it contains facts of importance to those that claim that childbirth is a simple physiological process, and to the few that hold that antiseptic midwifery and meddlesome midwifery are synonymous terms.

The profession will remember the astonishment, not to say incredulity, caused some eighteen years ago by Dr. Matthews Duncan's conclusion from careful investigation that "not fewer than 1 in every 120 women, delivered at or near full term, die within the four weeks of childbed." The late Dr. Farr, who in 1856 had declared the mortality of childbed in England and Wales to be 1 in 189, at first denounced Dr. Duncan as an alarmist, but before he died he admitted that the mortality was 1 in 129. From the Registrar-General's returns of puerperal mortality in England and Wales, it is seen that in the three years 1867-69 there were 2,228,588 children born alive; the deaths from childbirth were 10,198 (from puerperal fever 3,343), being an average mortality per 1000 of 4.37. In the three years 1884-86 there were 2,704,886 children born alive; deaths from childbirth 12,673 (6,966 from puerperal fever), giving an average mortality per 1000 of 4.68. While it is most probable that the figures of the Registrar-General are below the truth, still we see that within the three years 1884-6 there was an average of 2,322 deaths from puerperal fever in England and Wales. Other, and we may say more reliable, statistics, go to show that puerperal fever is accountable says Dr. Cullingworth, for from 65 to 75 per cent. of all the deaths from childbirth.

It is almost one hundred years since Dr. Alex-

ander Gordon published his account of an outbreak of puerperal fever that occurred in Aberdeen in December 1789–March 1792, giving a table of 77 cases that came under his own care. He showed that the midwives, nurses, and physicians were directly responsible for the continuation and spread of the disease and said: "It is a disagreeable declaration for me to mention that I myself was the means of carrying the infection to a great number of women. . . . I arrived at that certainty in the matter that I could venture to foretell what women would be affected with the disease upon by hearing by what midwife they were to be delivered or by what nurse they were to be attended during their lying-in, and in almost every instance my prediction was verified." We have similar testimony from Mr. Robertson, of Manchester, in regard to an outbreak in the maternity department of St. Mary's Hospital in 1830, due to one infected midwife, and from Mr. Blackmore in regard to an outbreak in Plymouth in 1831. In 1847 the mystery was cleared up and the first seeds of antiseptic—or aseptic—midwifery were sown by the immortal Semmelweiss.

Nothing has done more to retard the acceptance of the principles of antiseptic midwifery, and thus the practice, than that "confession of ignorance, the creed of fatalism, the very pessimism of obstetric medicine," the doctrine of autogenesis. It is impossible to see how anyone can read the statistics from the Lying-in Hospital of Vienna, from the Dresden clinic, the Paris Maternité, the New York Maternity, the Boston Lying-in Hospital, and other institutions, without being convinced of the utter fallacy of the theory of spontaneous infection. No stronger arguments can be brought forward than the facts and figures already at hand. Let us look at some of these figures of pre-antiseptic and antiseptic periods. In the Vienna Lying-in Hospital from 1863 to 1880 the rate per 1000 from puerperal fever was 11; in 1881–1885 it was 4. In the Dresden clinic the mortality per 1000 from puerperal fever was 8.7 in 1884, 1.4 in 1885, 1.4 in 1886, and 0.7 in 1887; in 1872 the mortality was 50 per 1000. In the Vienna Hospital from 1881 to 1885 there were 15,070 deliveries, with 2543 obstetrical operations, including 9 Cæsarean sections. In the Dresden clinic out of 2,775 women delivered in 1886–87, 396, or 14 per cent., required operative interference; 27 of the patients had eclampsia,

23 had placenta prævia, and 224 had well-marked contraction of the pelvis. In 1886, 77.8 of the patients in the Dresden clinic made perfectly normal recoveries, and 95 per cent. in 1887. In 1883 the mortality per 1000 from sepsis in the New York Maternity was 60.6. The antiseptic midwifery was inaugurated in the institution, and in 1884 the rate fell to 5.9, to 1.8 in 1885, and was 2.1 in 1886. In the Boston Lying-in Hospital the mortality from sepsis was 55.5 in 1882, 45.8 in 1883, 16.1 in 1884, 6.4 in 1885, and 0 in 1886.

A little more than a year ago Koch said that septicæmia was beyond the grasp of the pathologist in Germany, as antiseptics had succeeded in almost exterminating the disease in that country! (Senn: *Four Months among the Surgeons of Europe*, p. 63.) In the lying-in department of the Bürger Hospital in Strassburg "the antiseptic precautions are so thoroughly carried out that puerperal sepsis has never been known to originate in the walls. A small building, isolated from the main building, serves for the reception and treatment of infected patients from the city and surrounding country, and here the student finds the only opportunity to study at the bed-side and the post-mortem room the infective diseases incident to child-bed."

There is still a notion abroad, says Dr. Cullingworth, (*British Medical Journal*, Oct. 6, 1888) that this question of puerperal fever is one that chiefly concerns the lying-in hospitals. But one would scarcely suppose that the 2,708 deaths from puerperal fever in England and Wales in 1886 were all hospital cases; as a matter of fact almost 66 per cent. of them occurred in counties where no hospital exists, and as to the remainder, the lying-in hospitals of England and Wales are so few that they cannot be accountable for more than a small number of these. In a country town not far from London, says Dr. Cullingworth, puerperal fever has singled out the patients of one local practitioner. For six months every patient he attended, except two, in whom labor was completed before his arrival, died of puerperal fever. "The only way to avoid this terrible mortality, and to avoid also the enormous amount of puerperal disease which, because it is not fatal, remains unrecorded, is for every practitioner in midwifery to recognize his personal responsibility in the matter."

BRAIN OVERWORK IN CHILDREN.

The Chicago *Tribune* says: Dr. Charcot, the great French physician, says that children under 16 cannot have their brains overworked. No forcing, he asserts, will get out of them more cerebral work than the brain will accomplish without fatigue. It is not till after the age of 16 or 18 that forcing becomes possible.

It is extremely doubtful if M. Charcot ever made such a statement as the above. Such an assertion is reckless, because one cannot draw a hard and fast line at 16 years of age. If all children of 16 were made on the same mould, all had the same muscular development, all the same amount of nervous force, and the same degree of brain-development, it might be allowable to make some definite statement of the kind quoted. But to quote M. Charcot as authority for the above is dangerous, since the outcome may be that children already overworked may be seriously injured by unthinking parents or teachers.

"PROTECTION OF THE MEDICAL PROFESSION."

The following significant communication appears in the *Lancet* of October 13:

"There can be no doubt that it is high time for the great body of general practitioners to take some steps to protect themselves against the present rush of men into the profession, which is out of all proportion to the numbers leaving it, and as a result of which medical men are reduced to practice all manner of shifts to gain sufficient to merely exist. Medical ethics are becoming a dead letter, and a once noble and honorable profession is becoming little better than a trade. It behoves every medical gentleman to exert himself to the utmost to save his profession from dishonor.

"I beg to offer the following suggestions for remedying the present condition of things: 1. That every member of the profession in Great Britain and Ireland be canvassed as to the advisability of forming an association for the protection of the profession. 2. That the number of candidates admitted into the profession by the various corporations be regulated according to the vacancies occurring in the profession, as is done in the army and navy. 3. That a fee be fixed below which a medical man may not charge, and if his client be unable to pay, let him rather give

his services for nothing. 4. That the remuneration of all appointments be regulated by a council of the profession, and that no man shall take an appointment in opposition to this council."

"Medical Ethics are becoming a dead letter." In spite of the assertions of some of our cis-Atlantic, no-ethics contemporaries, we have here evidence that there is a Code of Ethics in Great Britain.

The suggestions offered by the *Lancet's* correspondent are more in the line of trades-unionism than anything we have ever seen proposed. An association for the protection of the profession would undoubtedly be a good thing if conducted on correct principles. Suggestion No. 2 would seem to be but a Utopian dream—if Utopian. The third suggestion seems unadvisable under any circumstances, would be productive of results almost as bad as are now complained of, and would stamp as paupers many people that are not paupers. And after all, the profession in England is not so overcrowded as in the United States,

EDITORIAL NOTES.

SMALL-POX IN ONTARIO has assumed such a threatening aspect that the Board of Health urges people that have not been vaccinated to be vaccinated immediately.

THE FACULTY OF MEDICINE OF PARIS received this year 373 Doctors of Medicine, including 327 French and 51 foreigners. On October 9th there were 3,668 male and 114 female students.

MENTAL ALIENATION IN NEW ZEALAND.—Dr. E. W. Alexander states that of 1,613 insane in the asylums in New Zealand, 1,302 are of foreign birth. Among the 111 native insane 21 are of the aboriginal or Maori race, which now number about 50,000.

NAPLES, it is to be hoped, will be more healthy when the now complete plans for its sanitary rehabilitation are carried out. The rookeries in four of its sections are to be demolished, and good dwellings erected. Drainage will receive careful attention, and the city is to have a sound and permanent system of water-supply.

DEATH DURING HYPNOTISM.—A Louisville paper says that at Hopedon, Ill., recently, Dr. I. N. Bishop extracted a tooth for his wife and at-

tempted to relieve her pain by an exercise of his mesmeric powers over her. He made a few movements over her face, when she screamed and fell dead. She was not subject to heart disease.

THE LOS ANGELES PEST-HOUSE seems to be in bad odor with the citizens of the place, according to the *Los Angeles Times*. It is badly in need of repairs, the residents in the neighborhood wish it removed, and threaten to get out an injunction against any repairs on it. The residents in the neighborhood where the new pest-house is to be located have already sworn out an injunction against the building of it.

EXPERIMENTAL URÆMIA IN PREGNANCY has been produced in pregnant rabbits by Drs. CHARPENTIER and BUTTE, with the view of determining the influence of uræmia upon the fœtus. They found that the fœtus died before the mother, the fœtal blood and tissues always containing a larger percentage of urea than those of the mother. The probable explanation is that the fœtus is unable to get rid of any part of the urea by excretion, while the mother can do so.

SINGULAR CASE OF SELF-MUTILATION.—A Dublin medical student, who had been subject to delusions for some time, recently removed both his eyes, and has refused to give any explanation of the occurrence. The act was committed in a field, where were found a blood-stained walking cane and a piece of wire, which were probably used to remove the eyes. The unfortunate young man was found lying down, about a hundred yards from the stick and wire.

TREATMENT OF PENETRATING SHOT-WOUNDS OF THE ABDOMEN.—DR. W. B. COLEY analyses, in the *Boston Medical and Surgical Journal*, 74 cases of penetrating shot-wound of the abdomen. Of these 29 recovered, giving a percentage of recoveries of 39.5. The cases are divided into three classes: Class I contains cases operated on within the first 12 hours; 39 cases—18 recovered; 43.6 per cent. recovered. Class II, cases operated on after 12 hours; 22 cases—5 recovered; 22.7 per cent. of recoveries. Class III, cases in which the time of operation could not be ascertained; 13 cases—7 recovered, 5 died, 1 doubtful; 57 per cent. of recoveries. The causes of death in the cases that did not recover were as follows: hæmorrhage 4 cases, peritonitis 9, shock 8, wounds not

found by operator 4, pneumonia 1, acute pericarditis 1. Dr. Coley's classification shows very clearly the advantage of an early operation, the percentage of recoveries in cases operated on during the first 12 hours being nearly double that of cases operated on after 12 hours.

LOSS OF MEMORY FROM AN ACCIDENT, while curious, is not so very rare. On October 30 Dr. Hillebrand, of Freeport, Ill., was exercising a colt. The horse became rather restless and unmanageable, and that is the last thing that the doctor remembers concerning the accident. He was discovered lying unconscious in the street, and immediately taken to his residence. Dr. Buckley was summoned without delay, and after examination discovered no bones broken. The left wrist was sprained and his face and head cut and badly bruised. It was some hours before he regained consciousness, but, as above stated, remembered nothing of the runaway, and even on the next day could not recall any particulars of the accident. The doctor is suffering considerable pain, and will be compelled to remain indoors for some time.

THE HAMMOCK AND THE SWING.—A writer in the *Chicago News* gives the result of an experiment, showing that the instinct of children has in it not only a love for recreation of a choice sort, but a sanitary common sense. A number of swings were suspended at a summer home for children, and near by were swung two dozen hammocks. The latter were almost always full, but the swings rarely were in use. The hammock is the most natural invention to give perfect rest and ease to the whole body, with a delicious sense of motion and activity. Every home should have several hammocks swung under trees, for the use of both adults and children. It will tend greatly to relieve the strain of everyday toil, and to sweeten the intercourse of its members.

THE MEDICAL STUDENT'S PARADE in Toronto on the night of October 31 ended in a serious affair. While the students were on their way home they stopped in front of the house of Dr. McCully, a specialist, who is dubbed a quack by the local profession, and commenced to groan and hoot. McCully appeared at an open window with a gun. This angered the students, and they commenced to throw bricks and stones. McCully then fired three times at them. Harry

Oldright, son of Dr. Oldright, received an ugly wound in the leg, and three others were slightly wounded. The gun was loaded with buckshot. Dr. Oldright swore out a warrant against McCully, and he was arraigned at the police court and remanded till to-morrow. The affair has caused great excitement.

A POCKET CLINICAL PNEOGRAPH has been devised by DR. MORTIMER GRANVILLE, and is manufactured by Weiss, of London. It consists of a delicately suspended and counterpoised semi-disc (made of talc), which rises and falls when the instrument is held over the mouth of a recumbent person, or swings vertically when held in front of the mouth of a person sitting or standing. The remainder of the apparatus consists of an arrangement similar to that used in the sphygmograph, by which the smoked paper is moved under a needle attached to the semi-disc. The tracing made by the needle is about as long and of a similar character to that made by the needle of the sphygmograph. The character of expiration is shown by the tracings, and some notable and apparently significant differences are seen in the results obtained in various pulmonary conditions.

THE ENGEL CREMATOR AT MILWAUKEE.—It has been decided to construct in Milwaukee a cremator similar to the one in operation in Minneapolis. It is thought that the cremator will be in operation by November 20. The furnace in Minneapolis is of the Engel pattern with numerous improvements. It is 32 feet long, 8 feet high and 5 feet wide. This is enclosed in a large building, inside of which are elevated drive-ways to the dumping spouts. The cremator is absolutely smokeless and odorless. The process of cremating is one of total destruction, all material being reduced to a fine, light-colored ash. At Minneapolis, while the Health Commissioner of Milwaukee visited the institution, six horses, a cow, and fifty dogs were dumped into the cremator, and in four hours had been reduced to ashes. The cremator, which has two fires, one to consume all noxious fumes, is capable of burning an unlimited amount of garbage or dead animals. Drawings have been made of the parts of the furnace for Dr. McIntosh, of Chicago, who will prepare them for the stereopticon. They will be shown before the annual meeting of the American Public Health Association to be held in Milwaukee the latter part of this month.

SOCIETY PROCEEDINGS.

Medical Society of the District of Columbia.

Stated Meeting May 16, 1888.

THE PRESIDENT, T. C. SMITH, M.D., IN THE CHAIR.

(Concluded from page 602.)

Dr. Swan M. Burnett was called to the Chair. DR. THOMAS C. SMITH read the history of

A CASE OF TRANSVERSE LACERATION OF THE CERVIX UTERI.

(See p. 665.)

DR. BUSEY: The management of the case was correct, and the result was satisfactory. Primary trachelorrhaphy was not now often practiced. It was not always free from danger, and the result was usually unsatisfactory. In very many cases lacerations of the cervix would heal without operative interference. The causes of this particular form of laceration were not easily understood. In this case there was, probably, a combination of circumstances and conditions. The labor was premature. The physiological changes which take place in the tissues of the cervix coincident with the progress of pregnancy had not been completed. The tissues had not reached that stage of maturity which promotes and facilitates dilatation. The amniotic fluid had escaped prematurely and consequently the dilating influence of the bag of waters was absent. There was also probably mal-position of the presenting vertex. In consequence of the rigidity and non-dilatation of the cervix and os extension was delayed or arrested, and the vertex was driven against the thinned posterior wall of the lower uterine segment at the point where the laceration began. In proper position of a vertex presentation in natural labors the vertex should occupy the center of the orificial dilatation. In this case it impinged against the attenuated wall of the lower segment posterior to the cervix. These three conditions may have been present. He suggested them as possible causes of the laceration.

DR. SMITH: Labor had not begun when he first saw the patient. The condition of the cervix was just as Dr. Busey had described it.

DR. KLEINSCHMIDT: Agreed with the explanation offered by Dr. Busey. In support of the statement of the unprepared neck he would call attention to the fact that it is more likely to tear in premature labor and abortions.

DR. SCHAEFFER: Might not the tear have been due to a brittleness or tissue-change at the point of rupture rather than to mal-position?

DR. SMITH: It is not usually found in primiparae.

DR. H. L. E. JOHNSON: Thought the case one

of rupture above the os uteri, and not laceration of the cervix as usually understood. Thought it suggested attempted abortion; that some instrument had been passed into the os rupturing the membranes prematurely and uterus at point of injury, or predisposing it to tear. It is unusual for the membranes to rupture so early in premature labor, that is, before any obliteration of the cervix or dilatation of the os, or with such slight pains, in the absence of mechanical interference. Dr. Smith does not state whether hydramnios or disease of the membranes existed, predisposing to rupture. That point should have been determined. He did not agree with Dr. Busey that rupture was caused by flexion of the head, as that is the normal and first part of the mechanism in L. O. A. presentations. Until flexion did take place the foetal head could not come in contact with the cervix uteri. He did not agree with Dr. Busey that exaggerated flexion caused the trouble, because the more flexion we have the more the small diameter of the head is made to correspond with the diameters of the pelvis. He agreed with Dr. Smith's treatment. The cervix should not have been operated upon at the time, and the result bears this out. He had examined a large number of patients between two and four weeks post-partum, and a large number of lacerations known to have occurred had healed—in some cases extensive bilateral lacerations. He had operated primarily on a case of lacerated cervix and the result was worse than the original injury.

DR. SMITH: In this case there was no deformity of the pelvis. At his second visit the child's head was in the position of flexion and was descending. The rapid transit of the head through the pelvic cavity would indicate that there was no deformity.

DR. C. W. JOHNSTON believed that in a certain proportion of the cases mentioned by Dr. H. L. E. Johnson, and in others of a like nature, where a laceration of the cervix seen immediately after labor, at a later date is found to have disappeared, the patient's condition after healing has taken place is no better than before such healing occurred. The angles of laceration in such cases have been closed by granulation and cicatrization, and it is doubtful if this kind of healing produces a more happy result than no healing at all. Theoretically it was quite possible for lacerations of the cervix to heal by first intention, and clinically cases are occasionally found where such union has occurred. If union by first intention, however, does not occur it may at least be considered immaterial whether healing by second intention subsequently takes place, or whether the parts afterward remain separated. In the light of what we daily observe as to the pathological moment of the so-called cicatricial plug, healing by any means other than first intention is not to be especially wished for. While a certain proportion

of our trachelorrhaphies are undoubtedly performed for the single purpose of uniting edges which have been disunited and have remained apart, yet still in a large number our main effort is directed to the removal of the cicatricial material which has been deposited in the angles of the wound—a form of healing which, as has been said, is of no value to the patient.

DR. H. L. E. JOHNSON: He thought it best to allow the wound to heal by granulation. Did not agree with Dr. J. that the cervix healed by granulation would present a cicatricial line which would give as much disturbance as if it had not healed, and require the operation ultimately. No such operation is required or has ever been done (*viz.*, stitching up a cervix which has healed and have it heal a second time by an operation). It is those cases lasting a long time and not healing, and in which histological changes have taken place and produce local and reflex symptoms which require surgical treatment for their cure. He could not agree with Dr. J. that a cervix could heal by first intention. Thought it impossible—a physical impossibility—as the lochial discharges would pass between the rent, and also the cervix being a muscular or musculo-fibrous organ its normal tonicity and contractility would separate the edges and prevent union by first intention. The pressure of the vaginal walls is insufficient to keep the edges in apposition. Nearly every parturient cervix is lacerated to a greater or less extent. Few require operation. The presence of these cicatricial lines is one of the points to be remembered in forming an opinion as to whether or not the patient had borne children. They cause no symptoms and require no treatment.

Philadelphia County Medical Society.

Stated Meeting, September 12, 1888.

THE PRESIDENT, J. SOLIS COHEN, M.D.,
IN THE CHAIR.

(*Concluded from page 641.*)

SYPHILIS OF THE LARYNX, TRACHEA, AND BRONCHI.

Diagnosis.—Differential diagnosis between secondary and tertiary lesion is sometimes difficult, particularly in the transitional period especially described by Whistler. The discriminating characteristics are less well marked in the laryngeal syphilis, perhaps, than in any other variety.

It may, however, be broadly stated that secondary lesions, erythematous, papular condylomatous or paralytic, are superficial; and that tertiary lesions are gummatous, ulcerous, carious, necrotic and deep-seated. Laryngitis occurring within a few months of infection is almost invariably secondary. Lesions appearing before the

termination of the third year are presumptive secondary; those appearing within the third year, secondary or transitional; and those appearing after the termination of the third year, tertiary. Nevertheless, secondary lesions may be ulcerous, and undoubted tertiary manifestations have been recognized even within nine months of infection.

The history of the case, and the previous or actual presence of manifestations of syphilis elsewhere, are the main positive factors in the diagnosis of specificity, especially in the earlier stages of either variety. The later lesions of tertiary syphilis are often sufficiently characteristic; sometimes not at all so. In cases of doubt, antisyphilitic treatment will almost always detect a lesion of syphilitic origin, but not invariably. Hence, in instances of strong suspicion, the various methods of antisyphilitic medication should be thoroughly tried before the test is abandoned. This suspicion is justifiable in cases of obstinate chronic laryngitis, whether ulcerative or not, in individuals in whom no other appreciable local or constitutional cause can be detected.

Laryngoscopic inspection is an invaluable aid in diagnosis; though practically indispensable, it is inadequate for fully appreciating the extent of deeply seated lesions; and its revelations are not always sufficient to establish the diagnosis in the absence of corroborative lesions elsewhere. Erythematous and catarrhal inflammation of secondary syphilis, when diffuse, are not to the ordinary eye distinguishable from similar non-specific conditions. Circumscribed erythema, though usual in syphilis, occurs in non-specific laryngitis also, consequently that condition alone is insufficient for discrimination. Patchy erythema on the vocal bands, and elsewhere, may be regarded as characteristic. Not so, however, the shaded pigmentations at the extremities of the vocal bands.

Symmetric bilateral localization of erythematous and other patches is highly characteristic of secondary syphilis; but a contrary condition by no means excludes the diagnosis. Isolated bilateral congestions of the supra-arytenoid structures and of the Wrisbergii has been cited as pathognomonic. Nothing can be more fallacious or misleading. Enlarged inguinal and post-cervical glands furnish excellent corroborative testimony of syphilis.

Papules, or condylomata, upon an erythematous mucous membrane, are to be considered pathognomonic. Their recognition may require an exceptionally good light on the one hand, or repeated examinations on the other. They must be carefully discriminated from minute collections of mucus or of saliva.

Diffuse gummosus infiltration is to be distinguished first from inflammatory syphilitic infiltration by the coexistence of gummosus processes elsewhere, its more circumscribed contour, and its sharper definition. Differential diagnosis is much easier after it has reached the stages of liquefaction and ulceration.

Syphilitic ulceration usually proceeds from above downward, rarely in the opposite direction, and often in extension from ulceration in the pharynx. Repair usually proceeds from below upward. Apart from these guides there is nothing positively characteristic enough to determine an ulceration to be syphilitic in character by mere inspection.

The absence of pain has been regarded as characteristic; but, on the one hand, carcinomatous ulceration often exists without pain, and on the other hand, the ulcerative lesions of syphilis are sometimes attended with lancinating pains of the most severe character.

In the gummatous stage of tertiary syphilis diagnosis is not difficult. They may be confounded with other neoplasms, and with abscess. In cases of doubt, antisyphilitic treatment should clear up the diagnosis. The physical distinction between gummata and condylomata may in some instances be obscure (Semon).

The main reason why gummata are so infrequently seen as to have led some observers to an erroneous opinion as to their rarity, is that many patients do not present themselves until after the stages of liquefaction and ulceration have become established. When this stage has not been observed, and the larynx, as is more usual, is not inspected until after ulceration has considerably progressed, the appearances are not always characteristic. They may be confounded with those of lupus, carcinoma and tuberculosis. The general diathesis, the clinical history, the existence of enlarged submaxillary and post-cervical lymphatic glands, the character of concomitant affections of the skin and mucous membrane, the aspect of the patient, assist in discrimination. Sometimes, too, tuberculous and syphilitic lesions coexist.

The typical tertiary ulcer, sharply defined, and below the surface of the mucous membrane, is more or less circular when recent, more or less crenated when reparation is taking place at one or more points of the circumference, and looking as though cut out with a punch when in cedematous tissues. Its borders are sharp, elevated, but not often undermined, and more or less rounded in their visible outline, and are surrounded by a more or less circumscribed inflammatory areola in the mucous membrane. The bottom feels hard to the probe on palpation. The bed of the ulcer is grayish, or lardaceous, yellow from fatty detritus, and covered with adherent concrete pus, through which, here and there, prominent rosy granulations often project. The surrounding tumefaction is harder and more indurated than in other varieties of ulcer. Purulent accumulations are rather indicative of the syphilitic process. At a later date denuded or necrosed cartilage may be visible in suitably located ulcers.

In cases in which neoplasms have become developed at the seat of existing ulcerations, or of

cicatrizated ulcerations or erosions, it is often impossible to pronounce as to their nature, even by the test of antisymphilitic treatment. Not only do such neoplasms exist independently of the syphilitic process, or as the result of irritation provoked by syphilitic process in the vicinity, but, when undoubtedly syphilitic in origin, they rarely disappear under specific medication. Tertiary syphilis is usually recognizable in the stages of œdema of the larynx; and almost always in the reparative stages of cicatrization, or in the subsequent stages of stenosis, whether from cicatricial retraction or from organization of effused products.

Prognosis.—Secondary lesions, even when ulcerative, are most frequently curable without cicatrix or without any other sequel. Exulceration of the vocal bands sometimes leaves permanent defect of tissue. The prognosis is good except during temporary conditions of œdema, when it may be grave for the time being. The inflammatory congestion and turgescence is more chronic than in catarrhal inflammations, and are often recurrent. Actual hyperplasia is apt to remain permanent, even after cure of the syphilitic lesion, despite the most assiduous treatment; and when it occupies a vocal band the voice may be permanently impaired. The singing voice may remain imperfect, although the conversational voice be fully restored; the injured tissues being unequal to the nicety of adjustment requisite for cantation.

In tertiary lesions the prognosis depends mainly on two factors: First, on the impairment of the general health, and the significance of lesions elsewhere, especially in the brain and meninges, and in other important organs. Second, in the extent of ulceration and the character of deformation or stricture which may follow. Temporary gravity exists in the presence of œdema; during the period of exfoliation of necrosed cartilages, and in acute bilateral paralysis of the dilator muscle, the result of exposure to cold or other cause, or to unilateral paralysis when the opposite side is immobile from gumma, or from crico-arytenoid ankylosis (Charazac: *Rev. Mens. de Lar.*, Sept., 1884), any of which conditions may demand prompt tracheotomy to prevent death by suffocation. Ulcerative lesions of the trachea may be fatal by hæmorrhage from penetration of large blood-vessels; by pneumonia from access of food through perforation of œsophagus (Berger); or by septic processes due to rupture of the mediastinum. Permanent impairment of the voice is to be expected in all cases in which the vocal bands undergo serious injury, and in many in which permanent changes are likely to take place in other structures contiguous to the glottis.

Gluttony is rarely affected, even after complete destruction of the epiglottis; and in exceptional cases difficulty is mainly confined to fluids swallowed without deliberation.

Stricture rapidly supervening upon hyperplasia is often amenable to active treatment, sometimes with striking rapidity (Krishaber: *loc. cit.*); but the more frequent stricture of slow progression can only exceptionally be brought under control.

Serious danger attends even cure of extensive ulcerative lesions in the interior of the larynx, for the resulting stricture, if severe, is likely to necessitate tracheotomy, with great probability of permanent retention of a canula. It is rarely amenable even to excision of cicatricial tissue by external access. Subglottic stricture is much more serious than supraglottic, and tracheal far more serious than laryngeal stricture. Stricture of the trachea, when low down, is practically insusceptible of amelioration; and death by slow apnoea, or by sudden suffocation, is the usual outcome.

When the syphilitic cachexia has advanced so far as to have produced incurable lesions in important viscera or in the cerebrum, death may ensue from these causes despite sustained cure of syphilitic lesions in the larynx. In cases complicated with paralysis of the dilator muscles of the larynx from cerebral lesion, the death may take place by occlusion of the glottis and suffocation, or by encephalitis and coma.

In hereditary syphilis the prognosis is very much the same as in tertiary syphilis; being much worse in infancy and childhood than in more delayed manifestations. The small size of the larynx renders stricture and intercurrent œdema far more significant; and the tendency to spasm of the larynx inherent to all laryngeal affections in childhood presents an additional element of danger. Fatal issues from these three causes are not infrequent. An element of uncertainty as to the final result remains in all varieties of syphilis of the larynx and trachea, due to the fact that permanent liability to recurrence prevails in many instances, despite the best apparent results of the most judicious treatment; and often, too, after prolonged intervals of immunity from any further manifestations of constitutional syphilis.

Treatment.—Fortunately, lesions even of great destructive and menacing tendency are amenable, as a rule, to treatment; often promptly.

The treatment, broadly stated, is that applicable to constitutional syphilis in general; mercury in the early manifestations and iodides in the late ones. In many of the latter, if not most, the mixed treatment combining the two specifics is the most serviceable. In congenital syphilis the gray powder is believed to be the most efficacious form of the drug. While willing to admit that secondary lesions often subside without traces and without much risk of subsequent tertiary manifestations, although mercury be withheld, I deem it the more prudent practice, and therefore best practice, to employ mercury; in the belief that its specific constitutional influence affords

the patient better protection as to future manifestations. As to the value of iodides in tertiary syphilis, there is no difference of opinion. Tonics are often indicated. All sources of irritation, exposures, excessive use of the voice, alcohol and tobacco, are to be avoided.

Sedative inhalations in vapor or spray are often of great topical benefit in subduing collateral inflammation; and antiseptic inhalations are indicated in gangrenous cases.

Secondary syphilis. Mercury may be administered by the stomach or by the skin. When the lesions are moderately severe or slow in progress, the corrosive chloride may be administered in doses of from $\frac{1}{16}$ to $\frac{1}{8}$ grain, three times a day. The green iodide may be given in doses gradually increased from $\frac{1}{8}$ of a grain three times a day to the point of tolerance. The addition of extract of belladonna may cause it to be better borne by the stomach. In individuals in whom serious gastric disturbance is produced before any specific effect has been noted, and in seriously severe cases and cases of rapid progress, inunctions of a drachm of mercurial ointment daily are preferable, or pencillings with solutions of oleate of mercury in oleic acid, 10 per cent. Lewin prefers hypodermatic injections of corrosive chloride. Concurrent stomatitis is to be combated by the internal administration of potassium chloride, or the use of a saturated solution of that salt, or of a weak solution of potassium permanganate as a mouthwash. It is hardly necessary at the present day to mention that salivation is to be avoided. In my own experience topical medication is, as a rule, superfluous in non-ulcerative secondary syphilis, and often unnecessary in the presence of ulceration. When topical medication seems necessary, inhalations of sprays of corrosive chloride (Demarquay) half an ounce or more daily of a solution containing 1 grain to 4 ounces of water are useful locally and constitutionally. In particularly obstinate conditions, especially in the presence of hyperplasias, the topical applications of solutions of iodine and potassium iodide in glycerine (Schnitzler) half a drachm and a drachm respectively to the ounce, made daily or at longer intervals sometimes accelerates the cure.

In the transitional stage and in the tertiary stages, the mixed treatment has been the most beneficial in my own practice; $\frac{1}{16}$ to $\frac{1}{8}$ of a grain of the corrosive chloride, 5 to 10 grains of potassium iodide in half an ounce or more of the compound syrup of sassa-parilla, three times a day. It may sometimes be necessary to increase the dose of the iodide up to the point of tolerance. In such cases the "grain to drop" solution is the most convenient preparation. The danger of inducing œdema of the larynx by sudden large doses must not be forgotten. When necessary sodium or ammonium iodide may be substituted for the potassium salt, or hydriodic acid may be employed.

In the presence of œdema, hypodermatic injections of corrosive chloride (Lewin), $\frac{1}{32}$ gr., twice a day for a day or two, and after improvement, at intervals of three days or more, have proved quite efficacious. If amelioration is not prompt, and if the patient cannot be carefully watched by an attendant competent to interfere in an emergency, it is best, in my opinion, to perform prophylactic tracheotomy, instead of awaiting its urgent indication. The same rule is applicable to threatening cases of extensive hyperplasia, whether from specific or from non-specific infiltrations.

Nevertheless, remarkably happy results, even in urgent cases of these kinds, have frequently followed active treatment by inunction (Krishaber) and by hypodermatic injection (Lewin). Intubation of the larynx from the mouth (O'Dwyer) has been recommended as applicable in many instances of œdema and constriction heretofore treated by tracheotomy. As yet, I know of no experience with intubation in this special connection.

Ulcerations heal more promptly when the constitutional treatment is seconded by topical cauterizations with fused silver nitrate, or with mercuric nitrate, 1 part to from 4 to 10 of water, or with cupric sulphate in crystal, or saturated solution. Chromic acid, 1 part in from 5 to 8 of water, has long been extolled (Isambert). Some prefer iodoform (Morgan). On the other hand, extensive ulceration often heals promptly under the influence of constitutional treatment alone.

Vegetations, detached flaps of mucous membrane, and semi-detached fragments of necrosed cartilage, call for operative removal with cutting forceps, evulsion forceps or snares, as may be most convenient, when these products are so located as to interfere with freedom of respiration or to threaten such interference. When these manipulations are impracticable, tracheotomy may be requisite. When tracheotomy has been performed under any of the conditions mentioned, the canula is to be removed as soon as it has become apparent that its retention is no longer essential to the safety of the patient. Cicatricial stricture of the larynx may be treated by the introduction of the intubation tube through the natural passages (O'Dwyer). This treatment may be applicable to stricture high up in the trachea. Stricture in the middle portion of the trachea requires low tracheotomy and the introduction of a tube long enough to reach beyond the constriction. Stricture at the bifurcation is hopeless.

Paralyses, even those of the posterior crico-arytenoids, are usually amenable to anti-syphilitic treatment even when of considerable standing. This fact seems to indicate that the atrophy found in necrotic paralysis is not due to simple inaction of the muscle, but rather to trophic impairments of neurotic origin. Electrization may be employed when relief does not ensue from systemic medication.

Membranous webs, occluding the glottis from side to side, are divided by incision or by galvanic-electric-cautery, the edges cauterized, and readherence prevented, if possible, by frequent introduction of dilating sounds. These laryngoscopic operations are often rendered futile by insurmountable tendency to recicatization, whereby the morbid condition is reproduced. Success in cases of this kind would seem to require exposure of the interior of the larynx by external division of the thyroid cartilage, and excision of the whole of the cicatricial tissue (Mackenzie).¹

When syphilitic laryngitis has existed for a long time, such an amount of destruction may have taken place, and such a degree of systemic poisoning, as to render recovery impossible. The constrictions produced by the cicatrices of extensive ulcers, and the adhesions between adjoining surfaces, in cases that recover, are often such as to render tracheotomy necessary, with the permanent use of the tube; for the constrictions following syphilis are not, as a rule, amenable to dilatation.

Threatened asphyxia or unconquerable dyspnoea, from gumma, loose cartilage, morbid growth, abscess, or œdema, may necessitate tracheotomy. Tracheotomy for the purpose of conquering dyspnoea due to tumefactions in the larynx is perfectly justifiable and usually successful. It is likewise justifiable for the mere purpose of securing rest to the organ—much more so, indeed, than in analogous conditions attending tuberculosis.

The treatment for local adhesions consists in relieving the tension as far as possible by laryngoscopic division of the constricting bands of tissue, with knife or with electric cautery, and then cauterizing and recauterizing the adjacent surfaces, to prevent fresh adhesions. These cases require careful watching and prompt attention to overcome the disposition to recurrence, which is very apt to take place in spite of all efforts. When the epiglottis is implicated, much good can be done by teaching the patient to move the organ frequently by means of his forefinger.

In a case of stenosis due to "concentric hyperchondrosis," as a result of the hyperplastic chondro-perichondritis, Prof. Heine performed a successful resection of the anterior portion of the thyroid cartilage, splitting that structure in the middle line, separating the perichondrium and superjacent soft tissues, to the distance of one-half its surface on the two sides, with the elevator, and then removing the denuded portions by longitudinal section with bone forceps. The patient rallied so well from the operation that an artificial vocal apparatus could be substituted for the ordinary canula on the fifth day. He became able to resume work after a while; but the disease made new inroads, and he died, 11 months later, in an advanced stage of tuberculosis.

Despite the most judicious treatment, and the most satisfactory immediate results, recurrence or recrudescence takes place in many instances at variable intervals, requiring resumption of specific treatment. The most satisfactory results claimed by any writer have been in cases actively treated by Lewin with hypodermatic injections. It is advisable to keep patients under observation for many months after active treatment has been discontinued. Mercuric iodide (biniodide) in small doses, one-twentieth to one-tenth of a grain, three times daily, may judiciously be given for prolonged periods during which apparent health exists. Potassium iodide, in diminishing doses, should be administered from time to time for a few days every month until the patient begins to show susceptibility to physiological effects from small doses; and then this susceptibility should be tested from time to time at intervals of a few months. Such supervision for two years at least seems to present the best prospect for riddance from the diathesis.

It may be mentioned in conclusion that, under intercurrent attacks of erysipelas, obstinate cases of tertiary syphilis of the larynx and trachea have undergone cure after having resisted all medicinal treatment.

Obstetrical Society of Philadelphia.

Stated Meeting, October 4, 1888.

THE PRESIDENT, T. M. DRYSDALE, M.D.,
IN THE CHAIR.

DR. JOSEPH PRICE reported his

RECENT WORK IN ABDOMINAL SURGERY.

There were 65 cases of operation, with 8 deaths, as follows:

Double pyosalpinx with double ovarian cyst and purulent peritonitis. Autopsy showed pyonephritis—7 days. Extra-uterine pregnancy. Moribund 36 hours before operation, 24 hours. Supra-vaginal hysterectomy for sarcoma of uterus and all abdominal viscera—4 days. Resection 20 inches of large and small intestine for carcinoma. Hopeless. 26 hours. Exploration and drainage. Large multilocular cyst right ovary. General malignancy. Parent cyst evacuated. Hopeless. Operation for temporary relief—4 days. Perforating typhoid ulcer. Evacuation of muddy fluid and lymph. Reacted well for 12 hours—36 hours. Hysterectomy for sarcoma of uterus and left ovary. Bowel involved—3d day. Strangulation of ileum. Released adhesions. Recurring attacks of collapse for three days before operation. Hopeless—25 hours. Total deaths, 8.

The mortality list gives a small group of these hopeless cases we are called upon to give some relief. In short they simply command you to do

¹ Med. Times and Gazette, August 19, 1871, p. 218.

something for relief. If there is one chance they demand it. As a rule they have been seen by one or many physicians, and have refused any early operative interference, or delay has been advised. We find in such cases just those pathological conditions that should at least induce us to recommend, nay more, to insist and urge the removal of all such murderous diseases. If all operators and practitioners recognized the importance of early operation in these and analogous conditions as they do in strangulated hernia, the mortality would be greatly reduced and a world of suffering saved. Early interference in ovarian cystoma is generally taught now. The importance of the early removal of the appendages in fibroid and myomatous uteri has not received that attention it deserves. The tubes and ovaries are diseased in a majority of these cases, and much of the suffering is due to their pathological condition. The mortality and the suffering in pelvic inflammations, the sequelae of gonorrhoea, are very great, and the country is covered with neglected cases. If cases carrying typical large pus tubes in this city were distributed there would be at least one in every street, alley and court. In my experience with small tumors in young women, I have been convinced of the propriety of early removal on account of accidents incident to their development and growth. Many are dermoids and prone to strangulation and suppuration, recurring attacks of localized peritonitis complicating their condition. I have been called upon to operate upon at least six of these young women in bed, emaciated, with quick pulse and high temperature. The general condition bad for so serious an operation as abdominal section. If these operations are done early while the patient is in fair condition, every risk of the operation is minimized—short anaesthesia, short incision, rapid enucleation, secure ligaturing, thorough irrigation and good drainage—the mortality will be very low and the much complicated and desperate cases rare.

DR. J. M. BALDY thought that such an opportunity, as was now presented by one of the cases presented by Dr. Price, should not be neglected, and that he would say a word about early operation in cases of tubal disease. A great deal of commendation had been expressed of these operations on the ground that very little trouble was likely to arise subsequently. The case referred to had been under the care of Dr. Daland and that he had had the pleasure of examining the post-mortem specimens with the doctor. The specimens, together with the clinical history, set the subject forward in a very vivid way. The history of the case was from the beginning one of tubal inflammatory trouble. Seven years before her last illness she had fallen into the hands of one of the oldest and best known gynecologists in the city, but who is not an operator. Dilatation and other well-known methods of treatment were

persisted in for months. Her real condition was evidently not recognized. She went on from bad to worse and finally in her last illness fell into the hands of Dr. Daland. She fell into collapse three times during this sickness and an operation was urged both by her attendant and the consulting surgeon; their hands were, however, tied by the consulting physicians. At the last moment an operation was agreed to but the patient died. The specimens and autopsy showed double pyosalpinx, with both ends of both tubes impervious. Intestines were bound down in a mass on the tubes, and strangulation had occurred. Such a condition of affairs should not have been overlooked by anyone, and an operation was strongly indicated. The case operated on any time during those seven years would have been saved with little risk. The case ran a course quite common, and which can only be prevented by early operation. In answer to a question from Dr. DaCosta as to how he knew there had been this condition seven years ago, he said that the woman had suffered continually with the same symptoms from the first. That she had either had the same condition then or it had been aggravated from a mild to a severe form of the disease by the treatment she had received.

DR. WM. GOODELL could corroborate the statement that the appendages were diseased in fibroid tumors. The larger the tumor the more likely are the ovaries and tubes to be diseased and the harder to remove. He was not sure but that in young women where the tumor was growing rapidly, it would not be better to remove the appendages early. Some years ago he had thought that dermoid tumors were solitary, but that two years ago he had removed a dermoid from each side, and had since noticed in the literature a number of others reported.

DR. M. PRICE said that the delay in treatment of many of these cases was due to the erroneous teaching in regard to inflammatory pelvic troubles. His belief was firmly fixed that they began as tubal trouble. In such cases leakage took place and set up other inflammatory trouble. He had been called in consultation to a case recently which was being treated as cellulitis, as usual. The patient had been an invalid for years; had been blistered, etc. The attack was relieved temporarily, but had subsequently returned and she was now in a bad septic condition. The tubes contain pus and the woman will either die of her trouble or be relieved by an operation. Her attending physician is a good man, but he has been taught that every trouble in the pelvis of an inflammatory character was cellulitis.

DR. HOFFMAN had lately come across a patient with fibroid tumor, who had been operated on three years before, but whose appendages had not been removed. She had great pain, and in one of our large institutions her trouble had been

pronounced *uterine neuralgia*. The operation revealed the colon adherent throughout almost its whole extent. Both appendages were diseased, and I had absolutely to dig them out. These difficulties probably caused the former operator to stop, and he would not have overcome them had it not been for the kind aid of Dr. Price.

DR. THEOPHILUS PARVIN exhibited a specimen of extra-uterine pregnancy removed by Mr. Tait in the latter part of August. Pregnancy was supposed to have advanced six or seven weeks. Rupture had taken place two days before the operation. The patient was doing well when he last heard of her condition, four days after the operation. He thought that Mr. Tait was really the most wonderfully expert abdominal surgeon he had ever seen. In his work no antiseptics are used; perfect cleansing of the hands with soap, water, brush and towel; perfect cleansing of the abdomen; incision through the skin and underlying tissues; hæmostatic forceps used if necessary, but frequently not required; the use of forceps to take up the tissues as the peritoneum is approached; the raising up of the peritoneum almost an inch so that there is no risk of injuring anything beneath the membrane; incision into the peritoneum; the moment the incision is made the introduction of one or two fingers or rather the index finger and the thumb. In this case the diagnosis was not positive, only probable, before opening the abdomen, but as soon as he had introduced the finger into the abdominal cavity, he said that it was a case of extra-uterine pregnancy with rupture of the tube. It took probably five minutes to bring up the ruptured cyst and ligate the tube with the Staffordshire knot. After removing the tube and ovary, water was poured in through a funnel to which was attached a rubber tube with a nozzle. The metal nozzle was pushed around in all parts of the abdomen so as to wash out all of the clots. In this particular case two pitchers full of water were used, a drainage tube was introduced and three stitches closed the abdominal incision. This patient did not have a temperature above 100°, and when seen three days later her recovery seemed almost absolutely certain.

DR. PARVIN also exhibited the following instruments:

THE AXIS TRACTION FORCEPS OF DR.
STEPHENSON,

Professor of Obstetrics in the University of Aberdeen. The forceps closely resembled the Simpson, being only a little longer and the pelvic curve greater. The traction is hooked on in front of the lock after the forceps is applied.

{ DELORE'S FLEXIBLE BLUNT HOOK; PAJOT'S
CURETTE FOR REMOVING THE REMAINS
OF A MISCARRIAGE,

consisting of a curette, the curve of which may

be altered while the instrument is within the cavity of the uterus and to which different sized extremities may be attached.

DOLÉRI'S ÉCOUVILLON

for brushing out the cavity of the uterus after incomplete abortion; before introducing the instrument it is dipped in an antiseptic solution. To this treatment its inventor has given the name of *écouvillonnage*. Sometimes the use of the curette precedes that of the *écouvillon*.

MATHIEU'S INSTRUMENT FOR WASHING OUT THE
UTERUS,

consisting of two tubes, lying closely together with small openings on their approximated surface. After introduction into the uterus the two tubes are separated by means of a screw, leaving a space for the water to flow from the uterus.

DR. WM. GOODELL thought that after seeing Stephenson's forceps he could justly lay claim to all priority in the axis-traction device. Many years ago in his work at the Preston Retreat, he found that his back so often gave out while making axis-traction with his left hand on the lock of the ordinary forceps, that he sewed a stirrup to the end of a leather strap. The other end of the strap he wound around the forceps handles near the lock and in the stirrup he placed his foot. He usually hung the strap so near the floor, that his heel rested on the latter, the traction force being made merely with the toes or ball of the foot. He thought Dr. Price had probably seen this impromptu device hanging on a gas fixture in the lying-in-room of the retreat. Of course the woman lay on her back with her nates drawn over the edges of the bed.

DR. PRICE remarked that he had seen the device spoken of by Dr. Goodell.

(To be concluded.)

DOMESTIC CORRESPONDENCE.

LETTER FROM NEW YORK.

(FROM OUR OWN CORRESPONDENT.)

Akromeglia—Infantile Hemiplegia with Epilepsy.

The first meeting of the New York County Medical Association for the season of 1888-89 was signalized by the presentation of the first case ever known on this side the water of the remarkable disease described for the first time in 1886 by Maril under the name of akromeglia. Dr. Adler, who exhibited it, first gave a brief sketch of the few cases of the disease which have been reported in Europe, and then went on to say that the designation of akromeglia, which simply meant enlarged extremities, was not a very satisfactory one; but it had now been generally accepted and,

in our present total lack of knowledge regarding the pathology of this affection, it would perhaps answer as well as any other.

The patient, a female, was a native of Germany, 34 years of age and married, and first came under observation in February last, at the German Hospital. Her mother had died from the effects of a fall, and her father was still living. She also had three brothers living, all in the enjoyment of robust health. She was strong and healthy, she stated, up to her 18th or 20th year, the time of the onset of her present trouble not being very clearly remembered. She began to menstruate in her 15th year, but the periods were always very irregular, and at the end of three years finally disappeared. She thought she was about 20 when she first noticed that her feet would swell from time to time; although a bandage or tight-fitting shoe, she said, would always readily reduce the swelling. About this time she also noticed some enlargement of the submaxillary glands.

The patient was unable to give any exact history of the present abnormal growth. She was married in her 20th year, and when she was 23 her wedding ring became so deeply imbedded in the tissues of the finger that it had to be sawed off. What she principally complained of all along was pain in the back and great weakness, and she was also subject to frequent attacks of migraine. The pain in the back she attributed to a long ride, from which she never recuperated. She had for some time been unable to walk, and spent most of her time in a semi-recumbent position.

On looking at the woman, Dr. Adler said, one was at once struck with the immense size of the head and the marked projection of the lower jaw. At the first glance it looked like a case of myxœdema or one in which there had been complete extirpation of the thyroid gland. The entire cranium was greatly enlarged, and the protuberance of the occiput was especially marked. The lower jaw was immense, and the tongue was greatly hypertrophied and flabby. There was no alteration in the teeth, except that those of the lower jaw were separated to some extent from each other; and the hair was abundant. All of the lymphatics of the neck were greatly enlarged. On a superficial inspection there was an apparent lack of the thyroid gland, but a more careful examination, especially during the act of deglutition, showed that the left lobe and the isthmus could still be distinctly felt, although the right lobe seemed to be wanting. No trace of the thymus gland could be detected. The clavicles were markedly enlarged, especially at their sternal extremities. The ribs were also greatly enlarged, and commencing kyphosis and a peculiar bulging shape of the chest, due to the costal hyperplasia, could be observed. There was comparatively little adipose tissue anywhere. The bones of the

arm and forearm also showed enlargement of the extremities, and there was some reason to believe that slight lengthening of the shaft had also taken place. The hands were also immensely enlarged, although there was no deformity of the nails, as has been noted in some of the other cases of akromeglia. The muscles everywhere were flabby and atrophied. The skin was markedly hypertrophied, but remained for the most part soft and pliant.

The same general condition of affairs was found in the pelvis and lower extremities. The feet were enlarged even more than the hands, being simply colossal in size, and in the legs there was also enormous hyperplasia of the epiphyseal regions and of the patellæ. It was noticed that there was marked hyperæsthesia in all the hypertrophied parts; even slight pressure causing the patient to wince. As regards the internal organs, a careful ophthalmoscopic examination failed to reveal the presence of any organic disease. Repeated chemical and microscopic examinations of the urine showed no evidence of any kidney trouble, and the red and white corpuscles of the blood were both found to be normal in number and appearance; although to the eye the patient seemed anæmic. The heart and lungs, and all the other organs, as far as could be ascertained, were entirely normal. The appetite was fairly good, but the bowels showed a tendency to obstinate constipation.

The electrical examination showed some departures from the normal. The resistance of the skin to the faradic current was enormous. Otherwise the cutaneous sensibility was not diminished. As regards the galvanic current, there was considerable diminution of electrical excitability, which was most marked in the peronei of both lower extremities. Still, there was no evidence of any degeneration going on in the nerves, and the want of electrical excitability could well be explained on other grounds. There was evidence of well-marked psychical degeneration in the patient, who was described as having been a bright and lively girl, but was very dull and apathetic.

Dr. Adler then made some general remarks on akromeglia, founded on the observations of European authorities. In most particulars, he said, this case corresponded very closely with those met with abroad, though there was one feature which was peculiar to it alone, viz.: the widespread hyperplasia of the lymphatics. As regards the post-mortem appearances in this affection, Klebs was the only author who had made anything like a satisfactory report. He had found a general hyperplasia of the connective tissue and marked proliferation of the blood-vessels. There was also enlargement of the various nerves, especially the ganglia of the sympathetic. In the brain he found well-marked hyperplasia of the hypophysis cerebri, and the question naturally arose whether there

was any connection between the enlarged hypophysis and the enlargement of the nerves. Klebs was inclined to attribute the disease to the proliferation of blood-vessels, but this was purely fanciful and speculative, and at present the true pathology remains shrouded in profound mystery. As regards the matter of prognosis, this was not particularly bad so far as life was concerned. In Europe two of the cases which had been first observed as long ago as 1867 were still alive. In some of the cases there were abnormal conditions of the heart. In most of them the thyroid gland was diminished in size or apparently wanting altogether; but in two it was markedly hypertrophied and was no doubt diseased. Amenorrhœa was a constant characteristic of the disease.

Dr. W. R. Birdsall expressed the great pleasure it afforded him to see this case, the first of its kind ever recorded in America. He did not think he could throw any light on the pathology; though there seemed to him to be some mysterious connection between akromeglia, myxœdema and extirpation of the thyroid. He said that he had at present under observation a young girl suffering from amenorrhœa who had developed some enlargement of the extremities of the phalanges of the hands, and to a less extent of those of the feet. It might possibly be an incipient case of akromeglia, but it was as yet too early to form a definite opinion in regard to it. As regards the electrical reactions in Dr. Adler's case, he thought that we ought to be very guarded in drawing conclusions.

Dr. Adler said that it seemed to him that the hyperplasia in and about the nerves might of itself offer a sufficient explanation of the diminished electrical excitability.

Dr. A. L. Carroll thought that profound gratitude was due Dr. Adler for the most admirable clinical demonstration which he had given of his unique case. Ever since he had first seen an account of this new disease in the journals he had been waiting in the hope that some one would find a specimen of it in this country, and it now afforded him extreme pleasure to have the opportunity of seeing the first case reported.

The question of treatment having been suggested, Dr. Adler stated that, in the total absence of knowledge of the cause of the disease, all treatment, so far as interference with its progress was concerned, was without avail. The patient was simply kept in bed and her functions regulated as well as possible. The attacks of migraine to which he had referred could always be sufficiently combated with antipyrin.

Dr. J. Lewis Smith then presented an interesting case of infantile hemiplegia accompanied with epilepsy and characterized by marked spastic contractions and slight athetoid movements in the fingers. In connection with it he read a communication concerning the case prepared, at his re-

quest, by Dr. M. Allen Starr, the well-known neurologist, in which the latter gave a *résumé* of some of the latest researches by Seeligmeyer and other authorities in regard to such conditions. In it he stated that all recent writers mention athetosis as a frequent complication of spastic infantile hemiplegia connected with epilepsy. On the invitation of Dr. Smith Dr. Birdsall then gave a clinical demonstration of the case and made some remarks upon it, in the course of which he stated that there was no doubt a destruction of tissue in the cortical areas, by reason of which the impulses from the brain were transmitted irregularly, and not in a coördinate manner. The last paper of the evening was by Dr. Daniel Brown, on "The Arrest of Secretions in the Eruptive Fevers," and this led to a valuable discussion by a considerable number of speakers.

BOOK REVIEWS.

PTOMAINES AND LEUCOMAINES, or the Putrefactive and Physiological Alkaloids. By VICTOR C. VAUGHAN, Ph.D., M.D., and FREDERICK G. NOVY, M.S. Philadelphia: Lea Bros. & Co. 8vo, pp. 316.

The subject of this volume is one of the greatest interest, for without doubt our knowledge of the causation of disease can be greatly increased by a more detailed knowledge of it. The full importance of ptomaines and leucomaines has been so recently appreciated that as yet many of the facts known to us are so scattered and isolated that a scientific appreciation of them is impossible. The present work will undoubtedly aid much in diffusing a knowledge of these substances in the profession, and in placing before the searchers after new facts all that pertains to the subject up to the present time.

The volume is devoted almost exclusively to the chemistry of these alkaloids. One can not but be impressed with our lack of knowledge of the physiological action of these alkaloids. This is a field widely open to the investigator, and one from which a rich harvest can be gathered.

No one in our country is better adapted to produce a work upon this subject than Professor Vaughan, for he has become an authority upon it from his original investigations into it, especially from those in regard to tyrotoxin, which he discovered.

THE APPLIED ANATOMY OF THE NERVOUS SYSTEM. By AMBROSE L. RAMSEY, A.M., M.D., etc. Second Edition. 8vo, pp. 791. New York: D. Appleton & Co. 1888. Chicago: W. T. Keener.

This work will be found exceedingly useful by all who come frequently in contact with those suf-

fering from disease of the nervous system. Its object is to aid in the anatomical diagnosis of such diseases. It is unusually complete in its treatment of the subject. Numerous diagrams and illustrations have been introduced in order to make explanations clear.

The present, although called a new edition, is practically a new book. It is much larger and for the most part newly written. If we were to make any criticism upon the book, it would be to urge the author to condense the subject-matter. So much of the substance of the work deals with the physiology of the nervous system that the title is somewhat misleading as regards its scope.

MISCELLANEOUS.

THE PREVENTION OF TUBERCULAR DISEASE.—The resolutions adopted by the Congress for the Study of Tuberculosis which assembled recently in Paris afford striking proof of the change which has come over popular pathological theories as to the etiology of this ubiquitous disease. It is not many years since the communicable nature of tuberculosis, and even the specificity of the process, were generally denied; now we find these two propositions taken as axiomatic, and important practical conclusions drawn therefrom to form the basis for legislation. In a courageous willingness promptly to accept the logical consequences of scientific discoveries, the French have frequently set an example which can only excite our admiration. Public opinion in this country and in our colonies moves more slowly, and the respect for vested interests leads to the perpetuation of practices which are injurious not only to the public health but, in the long run, to those interests which it is intended to conserve.

The first resolution led up to a *coup de théâtre*, no doubt carefully prepared beforehand. This resolution, which was adopted at an early sitting of the Congress, declared:

"That every means, including the compensation of owners, should be taken to bring about the general application of the principle that all meat derived from tubercular animals, whatever the gravity of the specific lesions found in these animals, should be seized and totally destroyed."

Now for the last three years the French Government has had in contemplation the advisability of applying the provisions of a law for the prevention of the spread of the contagious diseases of animals, passed in 1881, to the case of tuberculosis, and the necessary decree was actually signed by the President of the Republic during the session of the Congress. This decree is in every respect a remarkable document; here we are only concerned with its sanitary significance. It provides that every ox, cow, or other animal of the bovine species found to be suffering from tuberculosis shall be isolated, and that the veterinary inspector shall be present when it is slaughtered, and make a report on the *post-mortem* appearances. The meat is to be condemned if the tubercular lesions are generalized; that is to say, if they are not confined to the viscera and their lymphatics, or if, being confined to the viscera, the greater part of one organ has been invaded, or if the serous surface is affected. The sale of the milk of tubercular cows is absolutely prohibited, and it can only be used for feeding animals after it has been boiled. No provision exists for compensating the owners of condemned animals, and the possibility of creating a fund for this purpose is at present much discussed. One suggestion is to require an owner to provide himself with a

"certificate of origin" for each animal which he possesses. It has been calculated that a fee of one franc would be sufficient to raise a fund large enough to compensate all owners, while the existence of the certificate would greatly facilitate the investigation of the source of epizootic outbreaks. Another plan which has been suggested is compulsory insurance.

Two other resolutions adopted by the Congress at the end of its last session are interesting as showing the direction in which public opinion is advancing. One of these was:

"That dairies ought to be subjected to a special system of inspection, with the object of ascertaining that the cows are not suffering from contagious diseases capable of being communicated to man, and that this system of inspection ought to be extended to all other establishments of the same class."

The full significance of this resolution will be perceived when it is remembered that in France tuberculosis is now included among the diseases legally recognized as communicable. The other resolution was to the effect that steps ought to be taken to spread among the public, especially in country districts, a knowledge of simple means of avoiding the danger incurred by the ingestion of the flesh or milk of tubercular animals, and of proper methods of disinfecting the excreta of phthisical patients, and objects contaminated by them.

A large number of papers on the nature and treatment of tuberculosis, and on the influence of heredity, were presented to the Congress, and the general scope of the discussions was sufficiently indicated by the letters of our Paris correspondent at the time. Without seeking to detract from the value of those clinical and pathological contributions, it yet appears that by far the most important work achieved by the Congress was the adoption of the resolutions which have been mentioned above. They deal, indeed, only with one element in the etiology of tubercular disease, but that not the least influential in its action, while practically it is the most important because its operation is most under control.—*British Medical Journal*.

MEDICAL EXAMINING BOARD OF VIRGINIA.—We are glad that THE JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION, of September 8th, editorially reviews the record of this Board up to a recent date, and very warmly commends its labors to the consideration of the profession. It advocates the establishment of like Boards in other States, and shows by an analysis of the Reports of the Virginia Board what good has been done the profession. It naturally drifts upon the influence of such Boards in leading to a higher education by the Medical Colleges of this country, and severely reflects upon the conduct of those connected with a college who oppose the effort of the profession to bring about a higher standard for medical graduation. Many sensible, strong points are made in that editorial which we regret not having space to reproduce in our pages.

In the issue of this official organ of the American Medical Association for September 22d, we find a cordial approval of the editorial referred to by Dr. William Osler, of Philadelphia, an eminent Professor in one of the Philadelphia Medical Colleges. With reference to the Report of the Medical Examining Board of Virginia, he correctly says: "To the schools, such a report is as the handwriting on the wall, 'Mene, mene, tekel upharsin';" to the profession of every State, an encouragement to persevere in the good work of organizing Medical Boards."

Such sentiments expressed by those practically possessed of authoritative utterance go far to encourage the organization in other States of Medical Examining Boards similar to those in Virginia and North Carolina. They also help to encourage the profession in these two States to keep their Boards up to the high standard of excellence to which they have attained. There has been nothing in the conduct of the Virginia Board—nor, as to that matter,

in the North Carolina Board—to cause the profession to regret their selection of its members. With very rare exceptions, the few objectors to the Virginia Board are easily tracked to connection with or personal interest in some medical college.—*Virginia Medical Monthly*.

CLIMATE FOR CONSUMPTIVES.—PROFESSOR KNIGHT, of the Harvard Medical School, read a paper not long ago before the Boston Society for Medical Observation, on the choice of a climate for consumptive persons. Some of the ideas advanced may be of value to our readers. Patients who have cavities in their lungs, and those who have severe hectic symptoms, especially if they are poor, should not leave home, nor should those who have any acute affections of the lungs do so during the acute stage of the disease.

If, in the early stages of consumption, complete cure can be hoped for, a climate is to be chosen in which the patient can remain throughout the year. If, on the other hand, nothing more than temporary relief and some prolongation of life are to be expected, a mild winter climate is recommended.

While consumption presents a variety of phases and conditions, making it impossible to lay down fixed and invariable rules, it may be said that in general the first object aimed at by a change of climate is to enable the patient to live an active outdoor life, for the purpose of assisting nutrition of the lungs, and this is best attained in situations at an altitude of 4,000 to 8,000 feet above the sea level.

Dry and pure air, a good proportion of clear days, and a rarefied atmosphere which compels greater activity of the respiratory organs, make a mountainous country the best for this purpose. Those for whom high altitudes may be recommended are:

1. Patients who show no more alarming symptoms than a morning cough and expectoration. For them Colorado and New Mexico are suited.

2. Those who have some consolidations of the lungs, but no cavity, nor any serious constitutional disturbance. For persons who exhibit such disturbance—a high pulse and temperature—a lower altitude should be tried first; say the pure regions of Southern Georgia for the cold months, and then, if there is improvement, a more elevated region.

3. Cases in which there is early and frequent hæmorrhage, without much other evidence of disease. The mountains are peculiarly suited to persons of this class; and

4. Persons who are recovering from acute diseases of the lungs. But in these cases great care should be exercised, lest the steps taken to ward off permanent pulmonary disease have an evil effect upon other organs weakened by sickness.

Patients in whom tubercular disease has invaded the larynx should on no account be sent to high altitudes. They need mild and moist climates, like that of Southern California. Moreover, those who have a tendency to irritability of the bronchial tubes, and nervous persons, do not do well in high altitudes. A very high altitude should not, as a rule, be recommended for any patient over 50 years of age.

A DISGRACEFUL JAIL.—In the last quarterly Report of the Illinois State Board of Health DR. RAUCH says: On the 14th of July I made an inspection of the Tazewell county jail, at Pekin, concerning which I subsequently wrote to the sheriff in unqualified condemnation of the structure. That portion of it in which the male prisoners are confined consists chiefly of a room 27x28 feet, and 8½ feet high; this is divided by heavy iron bars into eight cells and, with its stone floor resting directly upon the ground, resembles a cage for wild beasts rather than anything designed for human occupancy. The only ventilation is by three apertures, 27x30 inches, fully one-third of the space obstructed by heavy iron-work. These aper-

tures are situated in the upper part of the wall, thus still further reducing their ventilating value, which is only nominally aided by two so-called air-shafts. Openings through the stone flagging in corners of the room communicate directly with shallow holes in the ground which constitute the only cloacæ. To empty these it is necessary to tear away the outside wall and then rebuild. The result may be imagined, but not described. Diarrhœas and low continued fevers prevail among the prisoners confined in this damp, noisome stone dungeon. If this jail is the result of a studied effort to outrage every law of health, humanity and decency, the effort is a disgraceful success.

THE WHITECHAPEL MURDERS.—Dr. Bloch, a member of the Austrian Reichsrath, has called attention to certain facts which may throw a new light on the Whitechapel murders. In various German criminal codes of the seventeenth and eighteenth centuries, as also in statutes of a more recent date, punishments are prescribed for the mutilation of female corpses, with the object of making from the extracted organs the so-called "diebslichter" or "schlaflichter"—"thieves' candles" or "soporific candles." According to an old superstition, the light from such candles will throw those upon whom it falls into the deepest slumbers, and they may, consequently, be useful to thieves. At the trial of a notorious German robber in 1810, it was discovered that a regular manufactory had been established by gangs of thieves for the production of such candles. That this superstition has survived among German thieves to the present day was proved by a case tried at Biala, in Galicia, as recently as 1875. In this the body of a woman had been found mutilated in precisely the same way as were the Whitechapel victims.

THE CINCINNATI POLYCLINIC was organized on October 31. It was first opened last Spring as a voluntary clinic, but it grew so rapidly that the idea of the present enlarged undertaking was soon developed. It is the first post-graduate medical school in Cincinnati and the fifth in the United States, there being two in New York, one in Philadelphia, one in Chicago and one in St. Louis. The present enterprise starts off most auspiciously, and has secured a registration of students in advance. The students are restricted entirely to graduates in medicine. The Faculty was organized with Dr. Chas. A. L. Reed, Professor of Diseases of Women, as Dean, and the following additional Professors: General Medicine, Drs. Kemper and E. W. Mitchell; Surgery, Drs. Wallace Neff and Longstreet Taylor; Diseases of the Eye, Dr. Robert Sattler; Gynecology, Drs. R. B. Hale and Edwin Ricketts; Diseases of the Skin, Drs. A. Ravogli and M. Ricketts; Diseases of Children, Dr. H. W. Rover; Diseases of the Throat, Drs. A. B. Thrasher and Boylan. Dr. Rufus B. Hale was elected Treasurer and Dr. Taylor, Secretary.

A GOOD MOVE RELATING TO POULTRY SELLING.—The State Legislature of Massachusetts has enacted the following: 1. No poultry, except it be alive, shall be sold or exposed for sale until it has been properly dressed by the removal of the crop and entrails, when containing food. 2. Whoever knowingly sells or exposes for sale poultry contrary to provisions of section 1 of this act shall be punished by a fine of not less than five nor more than fifty dollars for each offense. The Boards of Health in the several cities and towns shall cause the provisions of this act to be enforced in their respective cities.

It would have been better, surely, to have omitted the words "when containing food," in the first section. The entrails always contain either food or the excrete refuse of it, containing numberless microbes ready to set up putrefactive or diseased processes.—*The Prophylactic*.

DR. JAMES CRANE, of Brooklyn, who died on November 1, was an old and honored physician of Brooklyn. Forty-three years of his life were passed in Brooklyn, so

that he belonged to the earlier professional circle so few of whose members survive. His practice was large. He was conspicuous in the medical societies and active in the hospitals, and he served as Brooklyn's representative in the Metropolitan Board of Health, and later as President of the Board of Health of this city. Through disability rather than because of growing age he had in recent years withdrawn from general view, but he will be remembered and regretted by many families who knew and esteemed him privately, by his professional associates and by citizens who recall his skillful and faithful performance of public duty.

SUED FOR MALPRACTICE FOR GIVING CHLOROFORM IN ECLAMPSIA.—Dr. J. J. Leppa, of New York, has been sued for malpractice. The plaintiff, an Italian woman, says that her brother, the patient, a boy of 15, went to work at his trade in a silk-twine and braid factory in the morning, and came home at noon complaining of a pain, and was shortly after seized with convulsions. She called Dr. Leppa, who gave him chloroform and ether. The boy had six successive convulsions. The anæsthetic brought him out of each, but at the end of the sixth he died. It is a well-known fact that chloroform is one of the best and most approved drugs in eclampsia; and this case seems to be a particularly unjust one.—*The Medical Record*.

SMALL-POX IN PHILADELPHIA.—A dispatch of November 3 says: Upon information furnished by a physician the local health authorities late yesterday sent to the Municipal Hospital a woman named Caroline Gabriel, who was suffering from small-pox. She reached New York last week on a Bremen steamer and came on to this city by railroad. Health Officer Patterson was to-day emphatic in his denunciation of the negligent conduct of the New York health authorities, as, from the condition of the woman when first seen by the physician who reported her case, she must have contracted the disease before leaving Bremen.

THE WESTERN BUREAU OF PRESS CLIPPINGS is an agency to furnish any one with newspaper and general periodical clippings upon any subject. It was organized by Mr. F. L. Hagadorn, an experienced journalist, whose address is Room 2, *Times* Building, Chicago. The subscriber has only to indicate what kinds of clippings he wishes, and they are sent regularly. It is a labor-saving institution for all classes of men, and as such deserves success.

THE SWEATING SYSTEM IN HOLLAND.—A Committee of the Dutch Chamber has recently reported that in that country the average factory day is from 13 to 14 hours, while the operatives work often 18, 24, and 36 hours at a time. The Committee also reports that infant mortality is increasing, technical improvements are neglected, and the inventiveness of workmen destroyed.

THE BACTERIA OF SEA-PHOSPHORESCENCE.—Professors Pflüger and Tilanus, it is stated, have discovered the bacteria that produce the phosphorescence of sea fish, and have cultivated them by Koch's method. In the dark the glass slide containing them is seen to be thickly strewn with luminous points.

PENALTY FOR HANDLING INFECTED CLOTHING.—The magistrates of Bootle, England, have recently fined two persons for removing infected clothing. In one case a man removed infected articles from the house in which his child had died of scarlet fever; in the other a poor woman pawned a quilt to buy food for her sick son.

A CREMATORY IN TROY.—The new crematory to be erected in Oakwood Cemetery, Troy, the gift of Mr. Wm. S. Earl, will probably cost \$150,000. It is to be of granite, 130 feet long and 70 feet wide, and will be a mortuary chapel and retort.

A RESEARCH LABORATORY for the Royal College of Physicians of Edinburgh has been recently completed. Cuts showing the arrangement of the rooms are given in the *British Medical Journal* of September 15.

SIR MORELL MACKENZIE'S BOOK, "The Fatal Illness of Frederick the Noble," has appeared in this country. It is published in America by Brentano, of New York, Washington and Chicago.

MEASLES have become epidemic at Wellsville, Ohio, and of such a malignant type that great alarm exists. In East Palestine alone over 100 school-children are down with the disease.

LIABILITY OF PARENTS FOR CHILDREN OVER AGE.—An English judge has recently decided that a parent who calls a physician to see a child over age (of age) is not liable for the doctor's bill.

CHILDREN IN FACTORIES.—The Assistant Inspector of Workshops and Buildings, of Findlay, Ohio, has found children eight years of age working in glass-making houses.

THE PUBLIC SCHOOLS of Athens, Ohio, are said to be closed on account of prevalence of diphtheria in that place.

Official List of Changes in the Stations and Duties of Officers Serving in the Medical Department U. S. Army, from October 27, 1888, to November 2, 1888.

Col. Elish I. Baily, Surgeon, and Capt. John J. Cochran, Asst. Surgeon, detailed for duty on Army Retiring Board to meet at San Francisco, Cal., for the examination of such officers as may be ordered before it. Par. 3, S. O. 253, A. G. O., Washington, October 30, 1888.

Major John H. Bartholf, Surgeon U. S. Army (Ft. McIntosh, Texas), is granted leave of absence for one month, on surgeon's certificate of disability. Hdqrs. Dept. of Texas, San Antonio, Tex., October 10, 1888.

Capt. Daniel Weisel, Asst. Surgeon U. S. Army, died at Ft. Sill, Ind. Ter., October 30, 1888.

By direction of the Secretary of War, Capt. William H. Arthur, Asst. Surgeon, is relieved from duty at Ft. Bowie, Ariz., and will report in person to the commanding officer, Ft. Bayard, N. Mex., for duty at that post. Par. 21, S. O. 250, A. G. O., Washington, D. C., October 26, 1888.

James D. Glennan and Alfred E. Bradley, appointed Asst. Surgeons U. S. Army, with rank of First Lieuts., to rank from October 29, 1888.

Official List of Changes in the Medical Corps of the U. S. Navy for the Week Ending November 3, 1888.

Medical Director A. L. Gihon, ordered to Naval Hospital, Brooklyn, N. Y.

Medical Director John T. Taylor, detached from Naval Hospital, N. Y., and to Examining Board.

PROMOTIONS.

Medical Inspector Adrian Hudson, promoted to Medical Director.

Medical Inspector Michael Bradley, promoted to Medical Director.

Medical Inspector Newton L. Bates, promoted to Medical Director.

Surgeon T. Woolverton, promoted to Medical Inspector.

Surgeon C. H. White, promoted to Medical Inspector.

Surgeon G. W. Woods, promoted to Medical Inspector.

Surgeon F. L. DuBois, promoted to Medical Inspector.

Surgeon G. H. Cooke, promoted to Medical Inspector.

P. A. Surgeon Howard Wells, promoted to Surgeon.

P. A. Surgeon D. N. Bertelette, promoted to Surgeon.

P. A. Surgeon J. H. Gaines, promoted to Surgeon.

P. A. Surgeon Ezra Z. Dexo, promoted to Surgeon.

P. A. Surgeon F. B. Stephenson, promoted to Surgeon.

ORIGINAL ARTICLES.

OCULAR TROUBLES AS INFLUENCED BY NASAL DISEASE.

Read in the Section on Ophthalmology, Otology and Laryngology, at the Thirty-Ninth Annual Meeting of the American Medical Association, May, 1888.

BY LEWIS H. TAYLOR, M.D.,
OF WILKESBARRE, PENNA.

"There is no new thing under the sun" has been truly said many years ago, and its application to the various papers read from time to time before this and similar Associations is in the main correct. For, while looking from a different point of view, we may sometimes seem to present certain subjects in new lights, it is nevertheless difficult for us to bring forth matter pathological and therapeutical that has not at some point been touched upon, and possibly ably handled, by others of our professional brethren.

When I first began the consideration of this subject, being led thereto by the perusal of one article, and the treatment in private practice of a number of cases that presented points of interest bearing directly in this line, I was not aware that much had been written upon the relation of ocular and nasal diseases. Had I been familiar with the numerous interesting and valuable contributions to this department of medical literature that have since fallen under my notice I should have hesitated somewhat before being willing to present to you a paper upon a subject already treated so ably and thoroughly by others.

Yet, after all, the field is comparatively a new one, and I have thought it might not be out of place to present, or re-present, if so it be, a few points for discussion, and by the relation of a few cases from my own experience call your attention again to a too much neglected field of our practice.

I will not weary your patience nor occupy your time with a review of the anatomical structures, so familiar to you all, of the nose and the eye. The close connection between the two is apparent to even the superficial observer, and that the diseases of the one might readily be affected by those of the other needs to the thoughtful mind nothing more than the mere statement to carry with it conviction of its truth.

We have all of us at some time had certain puzzling cases, with annoying ocular symptoms that would not yield readily to our ordinary treatment. It may have been certain forms of phlyctenular conjunctivitis, keratitis, trachoma, irritable, dry or sticky lids, with harsh, rough, uncomfortable feeling, some forms of blepharitis, injected lids with enlarged marginal glands, photophobia with neuralgia, or other forms of disease with pronounced ocular symptoms, that we have treated as we do ordinary cases until our failure to influence their course has led us, if we have been wise in our day and generation, to seek the cause of the trouble outside of the eye itself, and we have found it quite often in the adjacent anatomical structures. Or it may be we are consulted by persons without apparent ocular lesions who complain simply of inability to use the eyes any length of time with comfort. A bright light is annoying, the printed page painful, and any continuous effort burdensome. A feeling of itching, fullness, lachrymation upon using the eyes, frequent headaches and other prominent symptoms are present; but when we make a careful examination we find vision normal, both near and distant, conjunctiva not especially swollen, perhaps a slight injection, ophthalmoscopic appearances good, and in fact we can detect nothing in the eyes to cause the troublesome symptoms. An examination of the nasal chamber reveals chronic rhinitis and very frequently hypertrophy of the membrane covering the lower and middle turbinated bones or a deviated septum causing an irregular enlarged passage on the one side, with an almost occluded one on the other. The connection between the eye and nose by means of the lachrymal duct is a direct one, and the lining membrane of the nose being thus continuous with that of the eye, we can readily understand how disease of the one might pass over, as we may say, to the other. Thus when a swollen mucous membrane with acrid discharge extends to the tear duct, partly occludes it, causes blepharitis of the lachrymal sac, and irritating conjunctivitis resulting therefrom, we can readily perceive the cause.

But there are other causes not so apparent. The tear duct is normal; it is patulous, there is no disease communicated from the nose to the eye directly, yet all the phenomena are here. Even

rhinitis is wanting. These are the reflex nasal phenomena so ably discussed by Dr. John N. Mackenzie and others. Sometimes the diagnosis by an inspection of the nose is apparent, but in others it is by no means so easy, and it may only be revealed by a careful and systematic treatment of the nasal difficulty. In my experience, however, the cases have been very few, of those coming under this category, in which a careful examination did not reveal the nasal lesion.

These cases are many of them subject to great variation in the intensity of the symptoms, but they are mainly characterized by lachrymation, injected, swollen conjunctiva, frequently passing into granular lids of the soft watery cedematous variety. There is generally irritation of the meibomian glands, with frequent perversion of the cilia, with yellowish secretion along the edges of the lids. Itching of the eyelids is frequently present. Photophobia not always. These are the patients that go from one physician to another improving slightly under local treatment, but readily relapsing into their old condition which seems aggravated by each additional cold they take. The oculist who studies and treats nothing but the eye will generally fail to give relief because the source of the trouble has not been detected by him and too often not even suspected.

The successful issue will depend mainly upon the proper management of the nasal affection, supplemented of course by a due consideration of what may be needed in the way of soothing applications to the eyes themselves; neglecting, by no means, general hygienic measures and systematic treatment when indicated. I desire here to relate the history of a few cases out of many that have proved interesting to me in the special study of these disorders.

Case 1.—Mrs. W. S., consulted me Dec. 17, for a chronic affection of the eyes which she and her husband declared had lasted nearly thirty years. It was also stated that she had been treated at various times by skillful physicians, also by quacks and old women, but without any permanent good resulting from the same. Vision in OD. $\frac{10}{CC}$ OS. $\frac{3}{CC}$.

This low vision being largely due to the presence of old corneal opacities. Her eyes are constantly weeping. This lachrymation is increased by any attempt at examination. Cornea is affected; it is rough and the epithelium in some places is apparently destroyed. Old opacities in both. Finely granular lids, cilia considerably affected and blepharitis existing in both eyes, with here and there quite large yellowish spots around the roots of the cilia. Altogether she seemed a most unpromising case for treatment. I gave her at first, atropia and weak zinc sulphate solution, prescribing also an alterative, and recommending the use of hot water to the eyes daily.

The treatment being continued in this direction

for a few days only, but with no apparent effect, I made a careful examination of the nose, which revealed the right side almost occluded by swollen membrane over the turbinated bones. There was a discharge of offensive yellowish material and the same had a constant tendency to drip in the throat. She had great difficulty also in breathing through this side of the nose. Vigorous treatment was at once instituted, and from this time on was directed mainly to the nasal condition. I used a spray of Dobell's solution for the purpose of cleansing, and applied the galvano-cautery freely to the enlarged turbinated bone. The left nostril was affected also but in less degree than the right. The cautery was repeated several times, the loop being more frequently used than the knife.

She improved rapidly. In one month the left eye was quite well and the right greatly improved. Early in April I removed with the cautery loop a polypus which had appeared in the right side during a cessation of treatment. The granular lids also were treated, chiefly by copper sulphate, alternating with tannin and glycerine. The improvement, as stated, was rapid and although the old opacities remain, and she is not entirely well, yet a very satisfactory condition is obtained from what seemed a very unpromising case. As a recent test V. in OD. $\frac{20}{CC}$ OS. $\frac{20}{XL}$.

Case 2.—Miss B., æt. 20, came to me in July, 1886, for treatment of granular lids and partial pannus, with watery rough cornea, especially in OD. I treated her for several months with silver nitrate, glycerole of tannin and various other procedures, be it said to my discredit, without treatment of the nose. She improved somewhat, so that I fitted her with glasses OD. + 1 cy. ax. 105°. OS. + 1.25 cy. ax. 75°. These gave some relief and she left town for a time.

The trouble was very obstinate and she returned in much the same condition as before. This was one of the cases in which inspection of the nares did not reveal rhinitis nor any considerable amount of fetid catarrh. But there was plainly shown an enlargement of the lower turbinated bones covered by almost normal membrane which pressed against the septum of the left side. Pressure readily lessened the swelling but caused increased lachrymation, as did any treatment of the nose. In the Spring of 1887 I began treatment of the nasal difficulty, in connection with the eye treatment, cauterizing freely the swollen turbinated membrane. The improvement was marked and rapid; OD. became entirely well in a short time, and OS. much better than it formerly had been. She left town for a time and lately has returned with a relapse in OS. which was not entirely well at the time of leaving. This is improving nicely under treatment.

Case 3.—Mr. L., æt. 25, V. OD. $\frac{15}{XX}$ OS. $\frac{15}{XV}$. He

has granular lids, especially in OD., which has pannus over about one-third of the cornea. The lids are velvety, granular and thickened. The meibomian glands are affected. He cannot possibly keep the right eye open. A gush of scalding tears follows every effort at examination. He has had this trouble for many years, and was treated with some relief by a physician seven or eight years ago.

Inspection shows hypertrophy of the nasal membrane on both sides, the right being almost occluded. Thinks he has had catarrh many years. Says his throat feels as if he had something in it all the time. He has granular pharyngitis (Oph.). OD. dimly seen, refraction about normal, but the fundus is greatly blurred. The upper part of cornea is blurred with pannus encroaching on the pupil. OS. nearly normal.

I advised daily treatment with spray to nose and throat, and glycerole of tannin to the lids with a collyrium of zinc sulphate to be used at home. After one week's treatment I advised atropia and bichloride solution at home, and I cauterized freely the right side of the nose.

Pupils dilated readily and I discontinued atropia. In another week he was much better. The cautery was applied two or three times and at the end of the month he was able to discontinue the bandage and resume his work. This patient is still under treatment but is improving rapidly.

Case 4.—Mr. C. L., æt. 22, OD. v. $\frac{20}{XX}$ OS. $\frac{20}{XX}$. Jr. I 5"—16" in each. No As. He comes in reference to his eyes. The lids are very finely granular, scarcely perceptible. He cannot use his eyes any length of time without pain and blurring. They water readily, and at other times have a hot, dry feeling. Oph. about normal in each. There was nothing in the condition of the eyes to suggest so much subjective trouble, but an examination of the nose revealed at once the source of the difficulty. He has nasal catarrh, which has become quite offensive. Membranes are swollen and passages partly occluded. I advised a weak solution of silver nitrate to the lids and spray daily to the nose. After a few days I applied the cautery to the left nostril. He has been under treatment but a short time but the improvement is already manifest.

From a perusal of these cases it is readily seen that in treatment much dependence is placed upon the careful but thorough use of the galvano-cautery, the application of which is rendered painless by the use of cocaine. Now, by thorough use, I do not necessarily mean the searing of the whole surface of both septum and sides of the nose, but the repeated application with small cautery knife or loop to a limited surface until at least a free breathing space is obtained and the ocular trouble removed. I have generally used the flat cautery knife, though I frequently prefer the loop, allow-

ing the wires to sink into the tissues, hoping by the healing of the eschar to obtain contraction of the tissues giving a free passage without destroying so large a surface of membrane.

I do not mean to say that every case of nasal disease will give rise to ocular troubles, but the chronic swelling of the membrane and the cavernous bodies underneath by which the turbinated bodies are pressed against the septum is very apt to give rise to reflex symptoms elsewhere. Dr. J. M. Mackenzie has shown that there are sensitive areas in the nose, especially over the lower turbinated bone, the irritation of which produces reflex symptoms in the eye, larynx, etc. We have all noticed how readily lachrymation is produced in certain individuals by the slightest touch of the nasal membrane, and it is readily seen that the constant pressure of a deviated septum against such must result in annoying and persistent symptoms.

The indication plainly is to get rid of this enlarged sensitive area. In addition to the cautery I have found in many cases good results from the use of nitric acid applied upon a cotton carrier as recommended by Dr. Lefferts, of New York. I have under my care at present a lad whose mother in bringing him to me for his first examination stated that he had used bottle after bottle of cocaine and it had done him no good except for the moment. This tallies with my experience. Cocaine is useless in such cases except for temporary relief.

A word as to prognosis. While I have in many cases seen rapid and satisfactory progress toward recovery as the result of the above mentioned treatment, I cannot report, as do some of our brethren, the healing of these chronic cases in a few days, and with but one or two applications. I believe the majority of them will require protracted treatment lasting for weeks, and even months, to effect permanent cures, with many relapses and discouragements. The most important point is the early recognition of such cases, and then their early and systematic treatment directed especially to the nose and not to the eyes.

The careful and painstaking physician will always examine thoroughly the nose in connection with ocular troubles, and those of us who are none too careful should at least receive sturdy hints to pursue our investigations further, when we see the ocular difficulty fail of improvement under ordinary local treatment.

SIXTEEN INCH CHEST EXPANSION.—The average chest expansion, as we know, is but little more than three inches; six inches expansion is very rare. The New York papers tell of a man in Brooklyn, an Irishman, 5 feet 10 inches high, and 45 years of age, who can expand his chest sixteen inches.

SURGICAL TREATMENT OF EMPYEMA IN CHILDREN.

Read in the Section on Surgery, at the Thirty-ninth Annual Meeting of the American Medical Association, Cincinnati, May 10, 1888.

BY D. A. K. STEELE, M.D.,

PROFESSOR OF THE PRINCIPLES AND PRACTICE OF SURGERY AND CLINICAL SURGERY IN THE COLLEGE OF PHYSICIANS AND SURGEONS, CHICAGO, ILL.

In presenting for your consideration the subject of the surgical treatment of empyema in children, I am sure that no apology will be necessary, when we consider that more than half the cases of empyema recorded occur during the first decade of life; and that more errors of diagnosis are made than in probably any other thoracic affection.

Definition.—By empyema we mean a collection of pus in the pleural cavity, the abscess bounded upon one side with the soft, receding, compressible lung, and upon the other side with the firm unyielding bony chest wall. And in the consideration of its surgical treatment, we must remember the ever-present surgical maxim, that "wherever we have a pus collection, it must be evacuated in the speediest, safest, and most thorough manner."

Causes.—It is not my purpose in this paper to enter into a consideration of the various causes giving rise to empyema, but I may state that in the majority of cases, it is my belief that a purulent pleuritis is due to auto-infection of a more or less limited area of the inflamed or damaged pleura through the medium of the general circulation; the pus microbe thereby gaining entrance and commencing its destructive action upon tissues that otherwise would only be the seat of a simple pleuritis. Other methods of infection are the use of unclean aspirating needles; rupture of a bronchus; extension of a septic pneumonia; secondary infection from the primary foci in some other point of the body; tubercular infection, etc.

Symptoms.—The symptoms, where we rely upon clinical evidence alone, are not sufficiently pathognomonic to be diagnostic. It is easy to determine by physical examination that we have a pleural sac distended with fluid, but its exact nature can only be determined by the introduction of a hypodermic needle (better of large size). If, following the usual symptoms of an acute pleuritis we have chills, fever, hectic, diarrhoea, and sweating, we are reasonably certain of our diagnosis without the aspirating needle. If these symptoms are accompanied by localized œdema or bulging of the intercostal space, usually the 5th in the mammary line, there is almost absolute certainty of pus in the pleura. The diagnosis may be made as early as the fourth day of the disease, although usually it is delayed until the second week or later. All cases of pneumonia that are tardy in undergoing resolution should awaken a suspicion of empyema. I have seen a

number of striking cases of error in diagnosis in cases of this character. Secondary infection of the pericardium is a fatal complication in a number of cases running a rapid course. A striking example of this mode of termination was recently detailed to me by Prof. C. W. Earle.

Empyema, if left to itself, may terminate in recovery in one of three ways according to L. Emmet Holt: (1) by spontaneous absorption of the purulent effusion; (2) by evacuation through the bronchus; (3) by opening externally through the intercostal muscles; but when left to nature the mortality is appalling.

Rilliet and Barthez mention thirty-three cases with four recoveries, twenty-one deaths, and eight not accounted for.

Surgical Treatment.—No absolute rule can be laid down for the management of all cases. We have our choice of operations from the following: For example, we may resort *first*, to aspiration; *second*, aspiration and washing out of the cavity with an antiseptic solution; *third*, thoracentesis with trocar and canula; *fourth*, thoracentesis with sub-aqueous drainage; *fifth*, simple incision; *sixth*, simple incision and drainage; *seventh*, simple incision with through and through drainage, with, or without, antiseptic precautions; *eighth*, subperiosteal resection of rib and drainage; *ninth*, thoracoplasty (Eslander's operation); *tenth*, peflation.

Which of these various methods will give the best results? As a matter of fact, as practical surgeons, we may confine ourselves to the relative merits of but two of these methods—aspiration, and free incision with drainage.

There is no question but that in a certain minority of cases in children, simple aspiration once or twice repeated, will effect a permanent and satisfactory cure.

I have the records of four such cases:

Case 1.—Charlie F., æt. 18 months; diagnosis, empyema, which was confirmed by Prof. H. A. Johnson; cured by aspiration; five ounces of odorless pus; died three years subsequently of malignant diphtheria. This patient was also seen by Prof. Waxham, and Dr. D. H. Sullivan.

Case 2.—Mamie S., æt. 30 months, treated for six weeks for chronic pneumonia by a distinguished physician; cured by one aspiration; twelve ounces of greenish pus withdrawn, very flaky; diagnosis confirmed by Drs. E. E. Babcock and T. K. Jacobs.

Case 3.—Baby, æt. 14 months; two aspirations; cured.

Case 4.—Infant (Home of the Friendless); empyema; two aspirations; cured.

Aspiration has the advantage of being simple, safe, and occasionally curative; but if we find the fluid re-accumulates, or septic symptoms are developed, then a free incision with drainage is imperatively demanded.

Aspiration has the disadvantages of leaving a small amount of pus for reabsorption, or which may become an inspissated residuum according to Abbe, that will result in a secondary abscess in after-life. Surgically considered, it is not as perfect an operation, or as scientific a procedure, as evacuation by a free incision and the introduction of a large sized drainage-tube.

Of 121 cases treated by aspiration alone, 23, or 19 per cent. were cured, six died, and the rest came to some other method of treatment, usually incision.

Incision.—Free incision, therefore, remains as the method possessing the decided advantages of complete evacuation of the purulent fluid, flakes of lymph, etc., and it moreover permits us to explore the cavity with the finger or sound and break down any septa or bands of adhesion. It permits of subsequent irrigation, if the septic nature of the fluid demands a washing out, and also gives us complete drainage.

The technique of the operation is comparatively simple; the diagnosis having been established beyond a doubt by preliminary definitive hypodermic aspiration. The field of operation is prepared in the usual manner for all aseptic operations. The point of selection for free incision and drainage is the posterior border of the axillary line in the 6th or 7th interspace, as in the recumbent position expansion of the lung tends to expulsion of the fluid at this point, although cases left to nature ordinarily point in the 5th inter-space, two inches to the outer side of the nipple. General anesthesia is usually not required, although a few whiffs of chloroform in nervous children are of advantage sometimes. But local anesthesia by means of the ether spray or hypodermic injections of from ten to fifteen drops of a 4 per cent. solution of muriate of cocaine answer every purpose in abrogating pain. The fold of skin at the site indicated is transfixed on a line with the upper border of the rib and incised for one and a half inches; then the intercostal muscles and pleura are divided, and as pus flows out in a full stream a large-sized rubber drainage tube is inserted and secured by safety pin, or by a button of rubber flange reflected so as to prevent its intrusion into the pleural cavity. The tube should not be more than three inches long. Irrigation should not be resorted to except in septic empyema where the fluid is fetid and caseous from bacterial decomposition.

I recently lost a patient during an irrigation with a solution of warm water slightly borated. The cause of death was probably due to a thrombus or obscure pleural reflexes causing shock.

As soon as the tube is introduced it should be covered with sublimated gauze so as to prevent entrance of septic germs, and the pus should be allowed to flow out upon absorbent cotton or antiseptic gauze, and the dressings changed daily. Strict antiseptic precautions are always necessary,

and our greatly improved results and lessened mortality are due to the antiseptic treatment now employed.

Contrast the different results: Depuytren operated in fifty cases with only four recoveries, while L. Emmett Holt reports sixty-three cases operated upon under full antiseptic precautions, with only two deaths. Of this number twenty-six successive cases were operated on by Goodhart and Taylor in the Eveline Hospital, London, with only one death, and *that* from a complicating pericarditis and peritonitis. The average duration of the discharge was about six weeks. In children we are usually able to discard the use of tubes in three weeks. When close apposition of the ribs causes flattening of the tube during pressure from coughing or induces neuralgia due to pressure upon the intercostal nerve, subperiosteal resection of one and one-half inches of the single rib will afford ready relief and better drainage; although my experience has been that it is rarely required. In old empyemas in children, or when we have a chronic abscess discharging through a sinus and shortening the life of the patient by lardaceous degeneration of kidneys, liver or spleen, or from general exhaustion, Eslander's operation of thoracoplasty should always be performed, although its field of usefulness is limited; but, if necessary, a sufficient number of ribs and a section of each should be made to permit the complete retraction of the divided ends of the ribs to the bottom of the cavity, thus closing it, otherwise a fistulous tract remains requiring a subsequent operation.

In regard to Ewart's method of perflation, reported last year, I have no personal experience.

In conclusion, therefore, I may summarize my observations as follows:

1. The surgical treatment of empyema in children is eminently satisfactory, and yields better results than in adults.

2. Multiple hypodermic aspirations are necessary to perfect a diagnosis, and should always be resorted to in cases of thoracic disease about which there is any element of doubt, especially in cases of pneumonia that exceed the usual period and become "old monia."

3. Aspiration cures a small minority of cases and should always precede a more radical operation, especially in localized empyemas.

4. Free incision and drainage, with local anesthesia, under strict antiseptic precautions, gives the most satisfactory results in the majority of cases.

5. Subperiosteal resection of the rib is sometimes necessary to afford perfect drainage.

6. Thoracoplasty is rarely required in children.

7. Other methods of treatment should be resorted to for special cases or circumstances.

8. Early incision, perfect drainage, and complete antiseptics should be the rule.

GYNECOLOGIST VS. GENERAL PRACTITIONER.

Read in the Section on Diseases of Women, at the Thirty-ninth Annual Meeting of the American Medical Association, May, 1888.

BY J. W. BROWN, M.D.,

OF MOTTVILLE, N. Y.

The able paper of Dr. Van de Warker upon proper methods of *instruction* leaves little to be said; but how shall we *practice* who are numbered with the rank and file of the profession, and are not so happily situated that the elegancies of specialism are obtainable? The general practitioner in the country has no sinecure. His attainments are well known, although but little from his pen appears in the journals, and he is not *invited* to elaborate pages of *theory* in the prevailing subscription treatise. His attendance at stated meetings of our various medical societies is uncertain; yet his opinions are none the less worthy of consideration, no matter how remote may be his location. With only a limited command of current literature and less time for its perusal, and with a meagre library, we find him working out these problems after methods of his own that demand recognition, even when unaccompanied by the erudition and culture of our cities.

Results are of more value to our patients, even if lacking the trade-mark of Vienna or Berlin; but how shall we obtain them? We all know to our sorrow the *magic* of the word "gynecologist" to our patient that pays. Imperceptibly she drifts from us. But how about the poor unfortunates who cannot afford this luxury, and whom we have with us always? To the wealthy, or those of modest means, the "private" hospital is always open, with skilled attendants, proper diet, regulated exercise, freedom from care, plenty of sleep; and, after weeks or months of special treatment, they return to us greatly benefited—sometimes (?) well, and at a cost that would wonderfully help the family physician; but *specialism is expensive*, and we therefore see the *cream* served upon the table of our brethren of gynecic renown, while we take *skim-milk* "in ours," and patiently listen to "how little country doctors know about female troubles," and are asked to wait when our modest bills are presented, as it cost *so* much for Dr. —. In the meantime what becomes of our poor patient (her husband mayhap a laborer), with a large family? She is anemic, with all the concomitants of typical nervous exhaustion. Does she ever get well? Is her progress any the less rapid than that of her more fortunate sister?

We all know what specialism accomplishes, and it is far from my desire to disparage it. We would indeed be in "*outer darkness*" were it not for the distinguished labors of American gynecologists. But what means shall we adopt when we cannot follow in their footsteps, not having the adjuncts at our command? Who is there in active country practice that has not some of these typical cases

who can barely afford the necessities of life. We have no hospitals at our disposal, and attendants are limited to some gossiping dame whose constant chatter drives them to the verge of distraction; the food is often improperly cooked and served in a manner that may be termed brutal; the little niceties of the fastidious nervous invalid condemned as fussiness, and a spirit of fretfulness developed by constant "nagging." It is useless to extend the tale—we all know it only too well; yet are our results any the less satisfactory? Is there not a tendency among our *confidères* of gynecological renown to ignore what general medicine taught them years ago, and attend only to the *special* features as seen by them, and by *their* influence through their patients affect the majority of women by calling attention to genital disturbances and thereby magnifying them? To us that cannot afford these luxuries and have not the time at our disposal for the dilettanteism of the profession, what shall we do? With the best means within our reach, *theoretically* our work is useless. *Is it so practically?*

What will best accomplish the cure of these poor nervous invalids, with no brain lesion, yet standing upon the border of "melancholia"—starving mentally, nervously and physically? Why does insanity in country districts make such rapid progress? We who spend our lives in farming communities know too well the monotony that is the lot of our poorer patients and, when accompanied with genital disturbances, makes their lives a curse and causes us more anxiety than profit. Shall we desert them because theoretical treatment is not attainable, and financially they cannot be removed from these influences and obtain the rest of body and mind so essential to recovery? Take our specialist from his idols and where is he? We must solve this problem ourselves, and I hope the discussion may develop much that we can apply to their alleviation. In their management, the merely negative man will not succeed. Be certain of your diagnosis, "then go ahead." Obtain their confidence or else abandon the case. Respect the hyper-sensitiveness, that is always present. Do not be arbitrary, as much depends upon moral suasion. Treat all genital lesions after recognized methods, adapting to the circumstances and surroundings. We have plenty of fresh air and, with pure milk and good diet, general debility can be slowly restored. Use tonics judiciously, but the mental starvation, associated with ovarian tenderness, engorgement, neuralgia and its legion of disturbances, must ever prove the obstacle that requires our most urgent efforts to surmount.

Neurasthenia is no myth, even among the poor or in remote country places, and the difficulties of cure will ever tax our utmost resources. Regulate menstruation and the abuse of sexual gratification. Divert attention from genitals, making light of their influences. Educate the will. Teach

self-reliance. Turn their thoughts towards recovery, not hypochondriasis. Make them understand that you will assist, *not* sympathize with every imaginary ache and pain. Trust them and encourage them in their effort towards recovery; even "if they fall by the wayside," try it again. Do not encourage morbidness, for we all know the craving for sympathy that invariably persists even when partially convalescent. Avoid drugs, especially anodynes, hypnotics and opiates. Treat upon general principles, no matter if it is old-fashioned. It is no sign of mental decrepitude if our patient retains her ovaries intact or trachelorhaphy has never been performed. Again repeating that, while admiring the skill and general worth of our brethren of special faith, they must always remember that general medicine is the *sine qua non* of success.

OBSERVATIONS ON YELLOW FEVER, WITH SPECIAL REFERENCE TO DIAGNOSIS, PROGNOSIS AND TREATMENT.

Read before the State Medical Association of Florida, 1888.

BY JOHN P. WALL, M.D.,
OF TAMPA, FLA.

The following remarks on yellow fever are based on clinical observations during the epidemic of that disease last fall in Tampa.

The etiology of this fever is but little, if any better understood than its pathology; and in these two points are to be found the individual characteristics, so to speak, of the disease. The idea of yellow fever being only a more malignant grade of malarial fever can only be entertained by very superficial observers, or those who have never passed through an epidemic of this fever. Notwithstanding this broad assertion it is not by any means easy, nor in fact always possible, to determine whether any single case is yellow fever or not; and this is especially the case at the inception of an epidemic. To arrive at a conclusion on this point quite a number of circumstances in connection with the case, apart from the symptoms, have to be taken into consideration; and then, reasoning by a process of exclusion, we may be able to approximate, at least, the probable truth. The recent history of the patient as to being exposed to infection in another place, on board ship or otherwise, and whether or not the patient has had a previous attack of this specific fever, are circumstances of the first importance to be taken into consideration. Though the patient may be from an infected place or have been otherwise exposed to the infection, yet if it can be positively established that he has had yellow fever, the probability of his having a second attack is so unlikely and remote as to warrant the exclusion of the yellow fever hypothesis in arriving at a diagnosis.

But where the patient has recently been exposed to infection and possesses no immunity acquired by a previous attack from this specific fever—in other words, is not acclimated—then, in such a case, there is a probability of its being yellow fever, and advantage should be taken of the doubt and the case managed as a case of yellow fever without waiting for a positive diagnosis. The management of such a case consists in the complete and thorough isolation of patient and attendants and, on the termination of the case, the prompt institution of measures for efficient disinfection of everything, even to premises, that might have been contaminated.

In its symptomatology yellow fever presents no well-marked indications of its true character in the beginning; nor, for that matter, at any time in mild cases, during its progress. Its attack is generally ushered in by a chill or chilly sensation, as in most other fevers and the pyrexia. With the rise of fever there is generally intense frontal headache, with pain in the small of the back and extremities, especially the legs. A feeling of tiredness in the legs, with a sense of general prostration, is usually experienced. Nausea from the beginning is not an uncommon symptom, though not always present. Incessant nausea with much retching or vomiting, during the first exacerbation of fever, indicates the case to be of a severe type. The tongue is generally coated with a white or whitish fur, is sometimes enlarged, and almost invariably presents red edges on the sides. The temperature for the first three days may range in different cases from 102° to 106° F., with a slight morning remission in the majority of cases. The pulse for the first three days may range in different cases from 90 to 110 per minute, though not so frequently above as below 100 beats per minute.

The skin is generally burning hot, rarely dry, and not unfrequently bathed in profuse perspiration. In many cases, after the fever sets in, the extremities remain cool, while the body heat is intense and pungent. And it is in this class of cases where mustard pediluvia or mustard sitz baths have been found so useful and beneficial in restoring the equilibrium of the circulation, as to render the mustard bath an almost universal remedy in the beginning of treatment. In severe cases albumin will be found in the urine on the *third* day, as a rule. Its presence is always a grave symptom, but as it is rarely—never in my observations—to be detected before the third day, it is impossible to determine up to that time whether the case is to be of a mild or grave type. In all cases where albumin is not present in the urine on the third day or at the expiration of seventy-two hours from the inception of the fever, the case will, as a rule, prove to be of a mild type, and the patient and friends can be assured of a speedy recovery if great prudence in eating and drinking is exercised for two or three days more.

And just here it is well to distinctly emphasize the fact that it is the acute parenchymatous nephritis, as indicated by the presence of albumin in the urine on the third day, which is the most marked characteristic of the graver type of this fever, and without which the icteric hue of the conjunctivæ and skin is rarely, if ever, developed. But it must be borne in mind that by no means do all cases of this fever, as it presents itself in this country, have albumin in the urine. And it is the presence of albumin in the urine on the third day, subsequently followed by the icteric hue of the conjunctivæ and skin, by which this fever can be positively diagnosed. These two symptoms—albumin in the urine and the icteric hue—at the proper time and in proper sequence, render the diagnosis of yellow fever as positive, from a scientific point of view, as it is possible to diagnose any other disease by physical symptoms.

The later writers and authors speak of albumin appearing in the urine in yellow fever, but fail to indicate at what time or stage of the disease the albumin is to be found; and they also fail to say that it is not present in all cases—two facts of the first importance. In the *London Lancet* of March 17, 1888, Dr. Robert Lawson, Inspector-General of the British Army, who had served in Jamaica, says: "On the evening of the third day, or morning of the fourth, the urine generally presents traces of albumin," thus confirming my observations as to the time when the presence of albumin in the urine may be expected. He fails to state, however, that albumin is not present in all cases of the fever, a fact of the highest importance in eliminating much of the confusion in regard to the diagnosis. In mild cases, where no albumin is found in the urine on the third day, the fever will terminate on the expiration of seventy-two hours, sometimes earlier, not to return, and the patient will progress to rapid convalescence without further trouble.

Yellow fever is generally described by authors as a fever of one paroxysm of seventy-two hours' duration, followed by a stage of apyretic calm of variable length, from one to twelve hours, and this is succeeded by the recurrence of fever of more or less intensity, accompanied with nausea and vomiting of white glairy mucus at first, then flecked with dark specks and shreds, which have been compared to bees' or butterflies' wings, finally terminating in the coffee-grounds-like black vomit. Now, as a rule, all of this is true of typically bad cases, but this secondary fever and nausea are very rarely to be met with in mild cases devoid of albumin in the urine on the third day. And in all cases in which there is no nephritic complication, as indicated by the absence of albumin in the urine, yellow fever ends on the third day, or perhaps earlier, convalescence practically sets in and recovery is soon complete.

Thus it will be seen that practically there are

two types or grades of this fever to be met with in an epidemic—one whose main feature is an acute parenchymatous nephritic complication developed by the third day; and the other which, having no such complication, ends with the first paroxysm of the fever and almost invariably terminates in speedy recovery, the patient being up and about as early as the fifth or sixth day. Not so, however, where albumin is detected in the urine on the third day; for while, in this class of cases, the high fever of the first three days may subside, and the pulse rate return to the normal, or even fall much lower, and the temperature be anywhere from 97° to 104° F., the patient still continues in a most critical condition, and not unfrequently so remains for an indefinite number of days. In some instances the temperature and pulse are normal, and so remain after the subsidence of the first paroxysm of the fever; but there are plenty of indications, and especially the albumin in the urine, to show the serious condition of the patient. It is doubtless this class of cases to which relapses are attributed by a certain class of physicians who are always trying to explain away why they failed to cure all their cases of yellow fever.

The amount of albumin in the urine varies in different cases, ranging from 5 to 75 per cent. of volume of the total amount; and, as a rule, the greater the amount of albumin, the more serious and less hopeful may be considered the prognosis. In these nephritic cases the eyes begin to show the icteric hue on the fifth day, and on the sixth or seventh day the skin begins to turn yellow. In rapidly fatal cases, terminating as early as the fourth or fifth day, the yellow hue appears earlier and is always well-marked after death. The yellow color which is characteristic of this fever in its worse and most fatal type, and has given the fever its name, is very rarely indeed, if ever, present in cases unaccompanied by the nephritic complication. This is repeated because it is a most important fact to remember.

Hæmorrhages from mouth and nose are not infrequent in the severe grade of cases having the nephritic complication. The urine may be tinged with blood, imparting to the coagulated albumin a dark color, but hæmorrhage from the urinary organs is seldom profuse; and as these hæmorrhages never occur in the paroxysm of the fever of the first three days, and only in cases with the nephritic complication, there should never be any trouble in differentiating yellow fever from hæmorrhagic malarial fever. The eyes become blood-shot in no inconsiderable number of cases. Epistaxis and bleeding from the gums are the more common forms of hæmorrhage met with in this fever, and the nose-bleed is often alarming. Among females passed puberty, more or less uterine hæmorrhage is almost certain to occur during the course of the fever, making its appearance

from the third to the fifth day. Even in mild cases this uterine hæmorrhage is rarely absent—and by mild cases are understood those without the nephritic complication.

The icteric hue of conjunctivæ and skin has very much the appearance of ordinary jaundice, though it is hardly likely that it is produced by the same cause—retention of bile in the blood—for the reason that bile is not very frequently found in the urine, as is universally the case in ordinary jaundice. One of the tests for bile in the urine is to add albumin and precipitate it with heat and an acid, when the coagulated albumin will assume a greenish color, imparted by the presence of biliverdin. In cases with the nephritic complication the albumin is already present in the urine, but it is only occasionally that the precipitated albumin assumes the greenish color of the biliverdin. From the time the yellowness of the skin becomes fully developed until it begins to fade, the capillary circulation is extremely sluggish; so much so, in fact, that firm pressure on the chest with the open and separated fingers leaves their marks on the surface for a number of seconds if not a full minute. Judging from the tendency to hæmorrhage and the capillary stasis which are such prominent features in severe cases of this fever, and taking into consideration the absence of bile in the urine in the large majority of cases, the conclusion is highly probable, if not positive, that this yellowness must be mainly dependent on pigmentation of the eyes and skin by the coloring matter of the blood, instead of being occasioned by the retention of bile in the blood—as in ordinary jaundice—as is generally supposed and believed.

Suppression of urine, or a very scant secretion more or less tinged with blood, only occurs in the third stage of the fever; rarely, if ever, during the paroxysm of the first three days. And it is only in this graver type of cases, with the nephritic complication, that suppression of urine takes place, to be followed by spasmodic twitchings, stupor, convulsions and death. These muscular twitchings are especially noticeable about the face. These nervous phenomena are supposed to be the effects of uræmic poisoning as a result of non-excretion of urea by the kidneys and its retention in the blood. But be that as it may, their occurrence is almost a certain prelude to a fatal termination, and in a prognostic sense is as bad, if not worse, than the black vomit. Hiccough is never met with in the first fever, *i. e.*, before the fourth or fifth day, and is a symptom of the most unfavorable import.

The injected and watery eyes, swollen face and anxious countenance so generally depicted by writers on this fever, may be noticed in a large number of cases, probably the majority. The detection of albumin in the urine on the third day of the fever and the subsequent icteric hue of eyes

and skin, establish the diagnosis of the fever beyond all doubt. But as before pointed out these two symptoms are absent in mild cases—those unattended with the nephritic complication—and hence the frequent disputes and contentions as to diagnosis in the beginning of an epidemic. The duration of the paroxysm of the fever for only seventy-two hours, or even perhaps a shorter time, and its abrupt termination without the use of quinine, should excite, however, grave suspicion of its character; and this suspicion will be greatly strengthened if the chill come on in the night, and especially in the latter half of the night. Dengue is the only other fever of our climate which may be ushered in by a chill at night, but its symptoms are too well marked—besides being a proverbially non-fatal disease—to admit of its being mistaken for yellow fever, or, *vice versa*, yellow fever being mistaken for dengue, by any one but the merest tyro in the profession—especially after a few days study and observation.

This brevity of the first paroxysm of yellow fever in mild cases, the subsidence of the fever without the use of quinine, the severe frontal headache, with pain in the back and extremities, and the absence of a second paroxysm of fever, taken with the appearance of the eruption on the extremities associated with dengue, will rarely fail to indicate to the experienced physician the true nature of the case. Many yellow fever patients emit a peculiar odor which the experienced physician has no difficulty in recognizing, though he may not be able to describe it by comparing it to any similar smell.

The matter of early diagnosis is a most important one in our Southern cities and towns as it is generally conceded, and my own experience tends to confirm this view, that if the first case (or cases) is recognized and proper measures of isolation and disinfection are instituted an epidemic may be prevented, especially in places whose atmosphere is not vitiated with miasmatic exhalations from accumulated filth. Hence the importance of ever being on the alert and carefully investigating any and every case of fever that comes under observation during the season when the fever usually prevails—the summer and fall of the year.

Daily observations should be made for the detection of albumin in the urine from the first to the fourth day, and if its presence is denoted on the third day the diagnosis is probable, and if on the sixth or seventh day there appears the icteric hue of conjunctiva and skin the diagnosis is positive. If the case is mild, however, but with the severe frontal headache and other symptoms already detailed, and abruptly terminates on the expiration of the third day, though no albumin may have been found in the urine, the diagnosis of yellow fever is only problematic, but the benefit of the doubt should be given to the community and all necessary precautions taken to prevent the increase and spread

of the infection. Of course the previous history of the patient, as to the probability of his having been exposed to the infection, and as to his ever before having had yellow fever, should be duly investigated.

As to treatment little need be said, as, unfortunately, so far no specific treatment has been found. The mild cases of the fever—those destitute of the nephritic complication—will, as a rule, get well spontaneously, with or without treatment, and it is probably because of the failure to recognize the two types of this fever pointed out in this paper that so many different remedies have been vaunted and then laid aside, and so much been said of different epidemics differing in their phases, and of remedies effective in some epidemics and futile or useless in others. The main indications are to restore the equilibrium of the circulation by mustard pediluvia or baths, evacuate the bowels with some efficient though mild purgative, and control the febrile excitement by the use of antipyretics—antipyrin and antifebrin. So far as my experience goes mercurials do not appear to possess any special advantage, except possibly that the stomach is not so likely to reject them as it often does more bulky drugs. Doubtless the common, though possibly erroneous belief that yellow fever is only an intensified form of bilious fever, and that the icteric hue is dependent on the same cause as that producing jaundice, and hence the fault laid to the liver, has always attached more importance to the use of mercury in the shape of calomel in this disease than experience justifies. Castor oil, or the more common salines, will be found about as good evacuants of the *prime vie* as anything else. Quinine is a useless drug in yellow fever unless there is some evidence of a malarial complication. It may be advantageously used during convalescence, but it is perfectly valueless in controlling the disease. Administered in mild cases, which would naturally recover, quinine often has received the credit of having cut short the fever as a *post hoc propter hoc* conclusion. The refraining from its use, even in mild cases, is advantageous in a diagnostic point of view, for if the fever spontaneously terminates by the end of seventy-two hours, or earlier, the presumption is against it having been of a malarial type. Antipyrin in 10 grain doses every three hours appears to have a very beneficial effect in reducing temperature, promoting diaphoresis, and relieving headache and other pains. Its advantages over antifebrin are its analgesic properties and greater solubility which renders its administration by enema in 20 or 30 grain doses almost as efficient as when administered *per os*. And this method of administration sometimes becomes necessary on account of nausea and excessive irritability of the stomach. The use of opiates is always hazardous, unless there was some way of determining anterior to the third day that no nephritic complication

would be developed, as their tendency is to induce suppression of urine. Of course in mild cases in which there is no albumin in the urine it is not certain that their use is hurtful, but the difficulty as to their use arises from our inability to determine this very important point as to the nephritic complication; and hence the safe rule is to eschew the use of opiates entirely in the treatment. An occasional exception to this rule may be made in cases presenting other complications and where the kidneys are not, or only slightly, affected.

As to food and drink, the less taken the better, so as to keep the stomach as quiet as possible. Cold drinks are decidedly injurious in the great majority of cases. Hot drinks are borne much better, and hence, doubtless, the common practice of administering lemon leaf and other teas. Possibly the benefit derived from these hot drinks is dependent on their constricting effect on the capillaries of the mucous coat of the stomach, on the same principle that injections of hot water are used in gynecology. For nourishment a tablespoonful of equal parts of milk and lime-water may be given every two hours, though if the patient is not naturally feeble "Tannerism," or starvation, may be practiced.

In the graver type of cases with the nephritic trouble, no line of treatment after the third day, promises any certainty of success. So long as the quantity of albumin in the urine remains comparatively small and the kidneys continue to act tolerably freely there is encouraging hope of the patient "pulling through," though there is no means of telling when or how soon the action of the kidneys will become fatally impeded or suppressed, and the case terminate in stupor, convulsions and death with or without black vomit toward the end. It is in this class of cases that we are constrained to recognize the impotency of our art and our utter helplessness in the presence of this dread disease. In this latter stage the tincture of digitalis in 10 to 15 drop doses every two or three hours may prove of some advantage as a heart tonic and diuretic. Of course, alcoholic preparations are indicated to sustain the flagging vital powers; but, unfortunately, like a great many other remedies, disappointment is only too frequently the result of their use. In the mild cases without the nephritic trouble alcohol is rarely indicated, it may be occasionally indicated in the nephritic cases where the quantity of albumin is small and the kidneys act fairly well, while in the worst grade of cases, it, like everything else in the way of remedies, is likely to prove of little avail.

No remedies proved specially useful in relieving nausea and hiccoughs. Cocaine was tried without benefit. Carbolic acid in small doses proved a failure. In fact nothing but as complete abstinence as possible from food and drinks appeared to do any good.

NOTE.—These observations are based upon 130 cases that I have treated myself, in which the urine was tested, besides seeing a large number in consultation where the urine was examined also. Dr. J. Y. Porter, who was here during the epidemic and had charge of the Fever Hospital and the Government relief measures, admits that his observations tally in the main with mine.

THE FORMATION OF AN ARTIFICIAL URETHRA FOR PROSTATIC HYPERTROPHY.

*Extempore Remarks before the Medical Society of Virginia,
Wednesday Evening, October 24, 1888.*

BY HUNTER MCGUIRE, M.D.,

EX-PRESIDENT OF THE MEDICAL SOCIETY OF VIRGINIA; SURGEON
TO ST. LUKE'S HOSPITAL, RICHMOND, VA.

After relating a case in which members of the Society were personally interested, Dr. McGuire said that this is the way that men usually die (by surgical kidney) who have serious obstruction to the passage of urine. In both sexes, and at all ages, mechanical obstruction to the passage of urine from the kidney ends in cystitis, ureteritis, pyelitis and pyelo-nephrosis. Obstruction may be due to stricture, enlarged prostate, tumor, stone, etc. It ends sooner or later in surgical kidney.

A very common cause for this is an enlarged prostate. This comes on after the age of 55 years. As far as Dr. McGuire's experience goes, if a man escapes this trouble until he is 63, he is not apt to have it. We all know how common it is in old men—so common that he sometimes wonders that it was not included in that wonderful description of old age found in the last chapter of Ecclesiastes. Possibly senile hypertrophy did not belong to that period; but is one of the results of so-called modern civilization. We don't know. We only know that hypertrophy of this gland is, with rare exceptions, peculiar to man. The prostate is a curious body; it is made up of fibrous, glandular and muscular tissue. It would be as well, if not better, to call it the prostatic muscle, than to call it the prostatic gland. It supports the bladder, which, otherwise, is so lightly and so feebly held in its position. The erect posture which man assumes puts a great strain on this body. Indeed, this might be used as an argument that it was intended for man to go on all fours, like the quadrupeds.

When deterioration of all the tissues begins—that is, about 55 years of age or more—this structure may commence to get bigger; it may enlarge toward the bowel, and do little or no harm. But if its growth encroaches in any way on the lumen of the urethra, then trouble begins. Put your finger into the patient's rectum, and you may find the prostate greatly enlarged; and yet

the man may have no evidences of urinary obstruction. And, on the other hand, the finger may reveal to your sense of touch no increase in the size of the gland; and yet there may exist marked prostatic obstruction. There may be new growths, tumors, true myomata which can be only felt by the finger in the bladder. The enlargement may be either centric or eccentric. You cannot reckon the extent of obstruction by the mere size of the gland felt through the rectum. All this depends upon the direction of the growth. Let it encroach, even slightly, upon the urethral canal, and lessen its size, and there soon follows irritability of the bladder, retention of urine, cystitis; and if this goes on, pyelitis and pyelo-nephrosis.

Dr. McGuire saw before him, as he was making these remarks, which he certainly did not intend to make, and for which he was entirely unprepared, many gray headed men who are listening to him with great attention. Some of you "old Fellows" may already know that your prostates are getting larger than they used to be; that it takes you a little longer to make water now; that it is slow to start; that the stream is not sent as far from your body, but drops down between your legs, which you keep wide apart to prevent your trowsers from being splashed. He advises you to try to empty the bladder every time you urinate, and not leave in it some residual urine which will decompose, just as it would do in a dirty chamber-pot, and afterwards set up in your bladder irritation and inflammation. Take care also to keep your body, and especially your feet, dry and warm. Don't sit on a cold stone or a wet saddle. Keep your bowels open, and let whisky alone. If the enlargement goes on increasing, and the calibre of the urethra is more and more diminished, more prominent and urgent symptoms are presented. Sudden retention of urine may occur, requiring the use of the catheter; or (and this is just as frequent) the patient will tell you that he cannot hold his water; that he has incontinence of urine. This condition generally means that his bladder is distended with urine, and overflowing; and the catheter is required here to relieve the over-distension. It would be out of place for him to talk about antiseptics and germs now. But it is not out of place for him to beg you to keep your catheter clean. A dirty catheter is a very dangerous instrument.

After a longer or shorter time, this enlarged prostate forms a dam at the outlet of the bladder, and only the water above the level of the dam escapes during micturition. Some urine, which is called "residual urine," is always left in the bladder. This decomposes, becomes ammoniacal, is an irritant and sets up cystitis. The poor sufferer strains violently to make water. This tenesmus of the bladder provoked by the obstruction, injures the vesical end of the ureters. These

tubes become involved, and the disease extends to the pelvis of the kidney, and presently to the kidney itself. Try to prevent this cystitis if possible. You may know that it is coming on by the irritability of the bladder; by the frequent calls to micturition; by his telling you that he never feels "like he is done" when he makes water; by his sense of weight, fulness and discomfort about his bladder, and by the other symptoms that have been mentioned. It is not worth while to try drugs of any kind, or dilatation by bougies to lessen the size of the prostate. Dr. McGuire has spent a good deal of time and money in endeavoring to reduce the gland by electrolysis. In his hands it has done no good. The only good you can do is by using the catheter—a clean gum catheter—letting the dirty residual urine escape, and, if need be, by washing the bladder clean with hot water. At the same time, you must attend to his general health and modes of life. Very often in this way the man will go on for months very comfortably. Sometimes the enlargement, if it be due to simple congestion and irritation, will pass away under this course, and the parts will be restored to their normal state. But if the enlargement be due to a true fibroma, or myoma, or if the hypertrophy be diffuse and fixed, then you may be sure the trouble will increase, and you will soon come to a period when palliation is no longer possible, and you must resort to operative measures.

It is wonderful how long a man may use the catheter, and the bladder retain its power of expelling the urine when you make a free opening into that organ. One of Dr. McGuire's patients has used the catheter for three years, never once in all of that time passing a drop of urine through the urethra without the aid of an instrument. As soon as an artificial urethra was made for him he could send the urine in a steady stream three feet from his body. In this case, the prostatic obstruction was so great that he often spent half the night trying to get the catheter into his bladder. When his bladder was opened, and the finger introduced, it was found that long-continued vesical tenesmus had pushed a part of the bladder down behind the prostate, making a pouch or cul-de-sac there, two inches deep; and in this pouch, what had not been suspected, a large prostatic stone. Dr. McGuire had sounded this man repeatedly for stone, and had not found it. A very short time afterwards another man was brought to his hospital—a poor old preacher who had been in bed for seventeen months with fearful cystitis from prostatic hypertrophy. He, too, was sounded as carefully as possible for stone, but none found. When his bladder was opened to make for him an artificial urethra, the first thing felt by the finger was a stone down in a pouch behind the prostate.

Dr. McGuire has operated for stone in the blad-

der, one way or another, 150 times or more, and this confession seems a strange one; but it is nevertheless true, and he believes before he operated in this way for prostatic hypertrophy that he has overlooked more than one case of stone in the bladder in such subjects. The first one of the patients referred to was one of the cases in which he had tried electricity, using an intense current after Apostoli's plan. When he put his finger through the bladder on this prostate, which was literally as big as his fist, and bad, along with this general hypertrophy, numerous large and small, hard nodular growths or tumors on its vesical surface, he felt how idle had been his effort to do any good in this way; and he has put out of sight and out of reach his expensive prostatic and vesical electrodes. If after what he has said about them, any Fellow wants them to try, he will cheerfully give them to him.

After you have exhausted the use of the catheter and palliatives generally, you must open the bladder and let the urine drain away, and give to the bladder and to the man, too, a rest which both sadly need. This is the only way by which you can possibly cure the cystitis and prevent disease from reaching the kidney. It is the only way by which you can stop the pain, or lessen the size of the prostate, or restore that man to anything like his normal condition. Now, how to do this?

The first time Dr. McGuire operated for stone by the supra-pubic method, he was struck with the fact that the bladder contracted as soon as an opening was made in its anterior wall, with a force sufficient to drive out every drop of liquid it contained, and that there was no more need for drainage tubes after supra-pubic cystotomy than there was after perineal lithotomy. The bladder is not an inactive bag, as you would expect to find it in a dead or paralyzed body. Its walls contain elastic and muscular forces which, in the natural state, are resisted by the same kind of structures at its outlet. But when an artificial opening is made in the bladder at any point, the muscular and elastic tissues in the walls of the organ contract and keep the viscus empty of any fluid. Recognizing this fact, he abandoned drainage tubes after supra-pubic cystotomy, as after many years we all were led to do after perineal section for stone. It was this principle that had led him to attempt the formation of an artificial urethra for prostatic hypertrophy.

The operation is very simple. You inflate the rectum with a rubber bag, which pushes the bladder up above the pelvic brim. Inject the bladder with water to make it prominent. Cut in the median line through the skin and superficial fascia from the symphysis pubis to a point three inches above. Separate, with the handle of your knife, the recti muscles. Cut through the transversalis fascia upon a grooved director. With the handle of the knife go through the fat and

loose cellular tissue in front of the bladder. Catch this organ, now exposed to view, with a tenaculum, and open it with the point of your knife. Carry your finger into the bladder, and examine it. Open the bladder as low down as you safely can—not higher than the top of the pubes. Let the water out of the rectal bag and remove it. The bladder will then fall back into the cavity of the pelvis. Take one or two stitches in the lower part of the wound through the skin. Don't include the muscles in your sutures. When completed, the opening in the bladder should be as low down as you can get it, and the opening in the skin at the upper end of the incision.

For several hours, to permit the wound to glaze, and for the sake of cleanliness, he uses a large drainage tube through this track. Keep the urine acid, for acid urine is aseptic, and this is the nearest approach you can get to antiseptic dressing in cystotomy. The urine will drain through the wound as fast as it is formed; and if all goes well for two or three weeks, the opening will be reduced to a fistulous track which will admit a good size bougie, say a No. 10 or 12, American scale. Now the man will begin to urinate through the fistula at will. He can retain the water two, three or four hours, and in one of his cases as long as six hours, without dribbling, and pass it when he desires. The fistula does not leak, no matter what may be the position of his body, unless he contracts his bladder to make water, or the urine accumulates to a point above the level of the top of the fistula. If the operation is properly performed, the fistula should be from $2\frac{1}{2}$ to $3\frac{1}{2}$ inches long, and occupy the same relation to the bladder that the spout of a coffee pot does to the pot.

The operation is so simple, comparatively so free from danger, involves no important blood-vessels nor nerves, is made at a safe distance from the peritoneum, and requires for its execution only a knife, a pair of forceps, tenaculum, and grooved director. Indeed, if carefully done, he has found it so safe that he does not hesitate to perform it in cases of diseases of the bladder where the diagnosis is difficult or impossible, simply that he may explore the bladder. If a laparotomy for diagnostic purposes is justifiable, the much less hazardous undertaking of making a supra-pubic cystotomy for the same purpose is certainly so. You will at least do this good: Drain the bladder and put it at rest, which in cystitis is worth more in one day than any drug or set of drugs would be worth in a month. It is astonishing to see how soon the patient begins to improve after the opening is made. The urine soon becomes free from mucus, pus and blood, which it formerly contained in such abundance. The vesical tenesmus and irritability rapidly pass away.

In one of his cases, a man 69 years old, so fee-

ble that he could, unaided, barely walk across the room, and reduced almost to a skeleton, in six weeks fattened fifteen pounds and could walk two or three miles without fatigue. This man got out of bed in sixteen days after being cut, and soon afterwards went about his business, wearing over the opening, to prevent chafing, a bit of absorbent cotton.

In his cases, Dr. McGuire had had, for the first two months, no trouble to keep the artificial track open. If the obstruction at the neck of the bladder is great, you need not expect the fistula to close at an early day, even if you introduce nothing into it. But at the end of about eight weeks, the prostate will diminish in size, all congestion and inflammation will disappear, and Nature will now make an effort to send the water through the natural urethra, and close up the artificial one. In the case just referred to, at the end of the eight weeks the man got up one morning, made an attempt to pass the urine through the artificial track, which was temporarily closed by a clot of mucus, and to his surprise, found the urine passing through the natural urethra. This was the first water he voided in that way for more than three years. Another interesting fact in regard to this patient: For the first time in ten years he has had a return of some sexual desire and power. All this goes to show the improvement which has taken place about the neck of his bladder. But at the end of eight or ten weeks the track must be kept open by the daily use of bougies, or by the introduction of a silver or a hard rubber plug as long as the artificial urethra, and about the size of a No. 8 or 10 American scale bougie. This should be kept in an hour or more every day.

NEURALGIA OF THE LINGUAL BRANCH OF THE RIGHT TRI-FACIAL NERVE.

Read before the Medical Society of the District of Columbia, May 27, 1888.

BY SAMUEL C. BUSEY, M.D., LL.D.,
OF WASHINGTON, D.C.

Mrs. A., æt. 63, has suffered for seven years with a painful affection, which she describes as follows: Six years ago, while residing in the State of Florida, after much reading aloud for several weeks, she was seized with an acute paroxysmal pain, beginning at the root of the tongue and extending along its right border to the tip. At first it came in quickly recurring flashes of momentary duration followed by longer or shorter intervals of complete freedom; but as the time passed the painful periods became more frequent, and the paroxysmal pains increased in duration and intensity until, finally, these periods would last for several hours, during which the pain would come and go. The first attack began in the autumn and continued until spring set in.

No method of treatment, either by local applications or internal medication, afforded any relief. Hypodermatic injections of $\frac{1}{2}$ grain of morphine failed even to mitigate the suffering.

During the six succeeding years, in the early autumn, with the beginning of the first cold snap, her suffering had commenced only to terminate with the coming of mild weather of returning spring. After the attack was over last spring she abandoned Florida as a place of residence, passed the summer in the North, and came to this city early in the autumn of 1887. As usual, during the past summer she was entirely free from pain and enjoyed her accustomed good health. In the month of November last, during an inclement day, whilst in a green-house, she felt the first twinge of pain along the right border of her tongue, which came and disappeared in less time than it took to tell of it. It, however, followed the course of the previous seizures, continuously increasing in frequency and intensity.

On December 10, I saw her for the first time. I found a lady of marked intelligence, with a bright and cheerful disposition, remarkably well-preserved, and with a history of unusual good health throughout her life. Her appetite was good, bowels regular, and habits of life regular and suitable for one of her age. There was no circumstance of life or physical infirmity with which her suffering could be associated in the relation of cause and effect beyond the facts stated by the patient and elicited by examination. During this interview, whilst narrating the history of her case, she was seized with the usual pains, sometimes at intervals of one and then of several minutes, which varied in duration from a few seconds to a minute or more, and in acuteness from a mere passing flash to momentary agony, which would be exhibited in distortion of the face expressive of great suffering, followed, as it suddenly ceased, with the returning smile of relief and the utterance of the words "gone again." These paroxysms of pain far most frequently began at the base of the tongue and darted along the right border to the tip; but sometimes one would begin at the distal end of the right anterior dental branch of the fifth pair; another in the inferior dental, behind the angle of the lower maxilla; then one would seem to start from numerous points on the right side of the face; but wherever the locality of beginning the pain always reached its maximum intensity and remained longest along the course of the right lingual. During pain conversation was always suspended, because of inability to articulate. Sometimes the interruption of speech would begin with the utterance of the first or second syllable of a word. The cessation of the darts, pangs and longer paroxysms of pain was as sudden as the onset, beginning without warning and ceasing at maximum intensity. There was no oscil-

lation with gradual increase in degree and gradual decline to ease. During the periods of painful seizures, which included several or many momentary or longer paroxysms of pain, the right buccal cavity became very dry, and the tongue was thickened and dry along the right border. During sleep the periods recurred less frequently and did not continue so long. There were fewer pangs or paroxysms of pain, but they were equally intense and sudden in onset and cessation.

The seizures were induced by conversation, drafts of air upon the right side of the face, by surprise, the unexpected entrance of a person into her room, a quickly spoken word by one not engaged in conversation with her, a startling noise, falling temperature or inclement weather, by attempts at chewing on the right side, by efforts to swallow liquids—unless the fluid was confined to the left buccal cavity—by every attempt to masticate and swallow bread or potatoes, and by every movement of the tongue which approximated it to the roof of the mouth. Meats could be chewed on the left side of the mouth and swallowed with facility and ease. I attempted, without success, to produce pain by pressure, rubbing and pricking the right border of the tongue and buccal surface, by jarring the upper and lower teeth on the same side, and by pressing, pricking, rubbing and pinching the external surface. Every attempt to produce artificially any condition similar or apparently identical with the current circumstances, before recited as exciting agencies, failed to induce a fleeting pang or paroxysm. For instance, the attempt to chew food on the right side would quickly induce pain, but the striking of the crowns of the teeth with a piece of metal or the pressure of the finger upon them failed. The movements of the tongue in articulation would, but the enforced movements of the organ would not excite pain.

The patient felt convinced that she was the victim of an incurable disease. All medication had failed; in fact, in very many instances she felt that her suffering had been increased by efforts to cure. She had tried a change of climate, place of residence and broken up a long established routine of life without securing relief. The pain began with the autumnal fall of temperature and departed with its rise in the following spring. Season seems to have been the constant and unfailing etiological influence. All the other circumstances and conditions were ineffective except during the season of inclement weather and low temperatures. The fluctuations of temperature, and sudden falls occurring during the seasons of rising and high temperatures, even when associated with inclement weather did not produce a period of suffering or even a paroxysm of pain. I advised the lady to have prepared a protector to cover the entire right side of her face, and suggested the trial of electricity.

My second interview took place December 14. She had kept the side of her face protected with a soft warm pad, lined with silk, but the periods of suffering had increased in frequency and duration, and the pains had increased in intensity. I then advised the application of a 4 per cent. solution of cocaine along the course of the right lingual nerve. The next day she expressed the opinion that the applications of cocaine had diminished her suffering, in that the periods of painful seizures had been shortened. I advised its continuance and ordered a mixture containing the salicylate of soda with the oil of gaultheria. This treatment was continued for one week without satisfactory results. I then advised the continuous use of morphia sulphate in $\frac{1}{8}$ grain doses, to be repeated at such longer or shorter intervals as might prove necessary to control the pain. The lady very reluctantly consented because she had lost faith in drugs, and was averse to the use of morphia. She did not follow the method of treatment very assiduously, but sufficiently so to obtain very marked relief. The months of January and February were passed in comparative comfort. With the returning mild weather of spring, the pain, as during the six previous seasons, entirely ceased. The best that can be said is that she suffered very much less than during the same season of either of the previous six years, but a cure cannot be claimed.

Perhaps, a more decided result would have been obtained if the plan of treatment had been more diligently employed.

The history of the case points very clearly to season as the predisposing and determining cause. In this particular there is nothing peculiar. But the curious array of accidental and incidental conditions which would produce longer or shorter periods of paroxysmal pain is certainly surprising, if not unique. Then, too, the paroxysms would recur during sleep, when the incidents detailed could not occur, either singly or concurrently. This fact also points to season as the predominant etiological factor.

Peripheral irritation produced by the movements of the tongue in speech, mastication and deglutition, and certain articles of food was a frequent and direct exciting agency in bringing on pain. Emotional conditions, such as surprise and the unexpected presence of a person, were equally effective. During sleep these influences were in abeyance and the paroxysms recurred much less frequently, but with equal severity. Sudden falls of temperature and inclement weather, during the autumn and winter seasons, even though the patient remained in-doors during such atmospheric changes, would also induce attacks.

The initial attack began under like conditions and circumstances for seven successive years, and followed the same course, the paroxysms gradu-

ally and continuously increasing in frequency, duration and intensity during the autumn and winter seasons, and ceasing abruptly with the beginning of spring-weather. The pain was always limited to branches of the right tri-facial, but the point of beginning varied. Far most frequently it began at the base of the tongue and was limited to the right lingual branch. When beginning at other points it was expended along the course of that nerve.

CANCER OF THE INTESTINE.

*Read before the Medical Society of the District of Columbia,
May 23, 1888.*

BY G. WYTHE COOK, M.D.,
OF WASHINGTON, D. C.

C. H., a mulatto woman, married, æt. about 38 years, was first seen by me on November 11, 1887. She gave the following history: She has always suffered more or less at her menstrual periods. About six years ago she had a miscarriage, since which time she has not been pregnant. Has suffered for a number of years from hæmorrhoids. Of late has had much pain in defecation. During last March she noticed an enlargement of her abdomen, and in May following her physician made a vaginal examination and introduced a sound into the uterus. Since that time she has not menstruated. She has been under the care of several physicians, but has continued to grow worse. She has been taking morphia and belladonna in suppositories to relieve her pain. She is now much emaciated and has had a diarrhœa for several days, her temperature is 102°. There is a fluctuating tumor just above the pubis and extending entirely across the abdomen. It is very painful to touch. Vaginal examination shows the uterus enlarged and fixed, but the examination is unsatisfactory, owing to the pain produced in the manipulation. No positive diagnosis was made, but medication was directed to the control of the diarrhœa; this was partially successful after a few days' treatment. A large hæmorrhoidal tumor, about an inch in diameter, was now protruding and caused much suffering. To relieve this the tumor was injected with carbolic acid and glycerine with most satisfactory results. The hæmorrhoid disappeared entirely and the patient expressed herself as much more comfortable than she had been for a long time.

After this the diarrhœa was pretty well controlled, and less morphia was necessary to soothe her pain, but there was no change in the abdominal tumor. A few days later I was told that a profuse diarrhœa had set in, and the discharges were described as being of a slimy, pasty character. I found the tumor much reduced in size, and I at once concluded that it was a subperitoneal abscess, and that it had discharged through the

bowel. From this time there was continued diarrhoea for four or five weeks, with temperature ranging from 100° to 103° , with a general typhoid condition. After this there was relief of the diarrhoea for a time, but the temperature continued elevated and abdominal tenderness persisted, notwithstanding the free use of counter-irritation and opium. The tumor seemed to fill up again and presented very much the same general characters that it did at my first visit. I was never able to make a thorough examination, owing to the great suffering produced by any manipulation of the tumor. There is nothing special to say regarding the progress of the case, other than that the patient steadily grew worse, with great pain in the lower part of the abdomen and pelvis and much intestinal disturbance. Her appetite was remarkably good, and she ate an egg and some bread and butter the day she died. This occurred on the 21st of April, 1888, from exhaustion. Several times during my attendance upon the case I suggested the advisability of a consultation, and expressed the opinion that some operation might be necessary for her relief, but the patient was unwilling for anything of the kind, so no consultation was held.

With the light of the autopsy before us, it is well that no operation was undertaken, for, aside from the malignant character of the tumor, it was so firmly bound down by adhesive inflammation that it would have been impossible to have removed it successfully. The specimen presents some interesting points:

C. Z. H.—mulatto, æt. 38, married. Died April 21, 1888. Necropsy by Dr. D. S. Lamb. Much emaciation. Pleuritic adhesions at apex of each lung. Both lungs showed abundance of cheesy masses, varying in size from that of a pin-head to nearly an inch in diameter, most numerous and largest in upper lobes, where also were many cavities, some of which communicated with each other. Heart small, normal. Liver, spleen and stomach normal. Lower end of ileum showed many small ulcers, near mesenteric attachment; a few similar ulcers in ascending colon. Mucous membrane normal up to within 4 inches of anus, where was a perforation $\frac{1}{2}$ inch in diameter, with congested margins. Nearly 1 inch higher up was another perforation, oval, transverse to axis of intestine, about two inches long and one wide, with congested margins. Both openings led into a sac the size of a new-born child's head, and containing soft dark feces. The wall of the sac was thin and generally covered with peritoneum; adherent to uterus, upper part of vagina, rectum, wall of pelvis, cæcum and several folds of small intestine. It was easily removed from the wall of pelvis. Inner surface of sac corrugated, looking like bands of involuntary muscle. For some distance around the perforations the sac wall showed a somewhat flattened growth,

about $\frac{1}{2}$ inch thick at the thickest part and ulcerated. Uterus normal; vagina normal; right round ligament normal. Fallopian tube and fimbriated end not distinct. Left tube visible for a short distance, then lost in the mass of adhesions; ovaries not visible. Kidneys normal. Bladder somewhat distended.

Dr. W. M. Gray, of the Army Medical Museum, says the cheesy masses of the lungs are tubercular, and the new growth near the rectum is cancerous.

ANEURISM OF THE ARCH OF THE AORTA AND SUBCLAVIAN ARTERY.

Read before the Medical Society of the District of Columbia, June 6, 1888.

BY JOHN B. HAMILTON, M.D.,

SUPERVISING SURGEON-GENERAL, U. S. MARINE HOSPITAL SERVICE; SURGEON TO THE PROVIDENCE HOSPITAL, WASHINGTON, D. C.

The following case of *aneurism arch of aorta and subclavian*, reported for me by Dr. Carmichael, M. H. S., occurred under my observation at the Providence Hospital, Marine Ward:

Gordon Fitzhugh (negro), æt. 48 years; nativity, Virginia; admitted to Providence Hospital, Washington, D. C., April 6, 1888; died June 1, 1888.

History.—He was first admitted to hospital on February 14, 1888, suffering from severe dyspnoea, coryza and acute laryngitis. Examination revealed the presence of a subclavian aneurism and regurgitant mitral disease of the heart. A murmur was also heard at the aortic cartilage, but it was partly obscured by the blowing sound of the aneurism. Under appropriate treatment the coryza and laryngitis subsided; while rest in the recumbent position and the administration of potassium iodide, in doses of 1.20 gm., relieved the distressing dyspnoea. He improved until March 2, 1888, when, at his own request, he was allowed to go to his home. On April 6, 1888, he was readmitted to hospital in great distress, and under treatment he again somewhat improved; but the paroxysms of dyspnoea recurred at shorter intervals; were more distressing, and his strength was much reduced. The pulsation of the tumor in the neck and the accompanying thrill and bruit were strongly marked. Auscultation revealed a loud murmur over the mitral area, transmitted towards the base of the scapula. He grew much worse during the latter part of May; delirium set in on the evening of the 31st, and at 11 P.M. he died.

Necropsy.—(Nine hours after death.) Body fairly nourished. Rigor mortis present. Brain not examined. Lungs emphysematous at the borders and congested throughout. Heart very large, and walls of ventricles show beginning fatty change (compensating hypertrophy succeeded by dilatation and fatty degeneration). The ascending and transverse portions of the arch of the

aorta were dilated into a large aneurismal tumor, and the right subclavian was also the seat of a large aneurism which, having ruptured, could not be removed from the body in its entirety, owing to the numerous and intimate attachments to the surrounding parts. The thymus gland was extremely large, and accompanies the specimen. The gland had evidently continued to grow during adult life. The heart was very large, and the walls of the ventricles the seat of fatty change; the tricuspid and pulmonary valves were healthy; the mitral was the seat of atheromatous patches and nodules, and the valve was incompetent. The semilunar valves of the aorta were thick, leathery, the aortic orifice somewhat narrowed, and numerous deposits of calcareous material were found on the valves near their margins. The liver was fatty in patches. The kidneys were congested and the other viscera were healthy.

MEDICAL PROGRESS.

WOUND OF INTERNAL MAMMARY ARTERY: HÆMATOMEDIASTINUM.—A remarkable case under the care of PROF. MADELUNG has been reported in the *Berliner Klinische Wochenschrift*, and in the *Centralblatt für Chirurgie*, No. 19, 1888. On September 2, a man, aged 39, was stabbed with a knife in the head, thorax, and abdomen, but little hæmorrhage was noticed. He walked one hundred paces, reaching his dwelling, where it was found that intestine had prolapsed through the abdominal wound. Twenty hours after the injury he was taken in a wagon to the Rostock Infirmary, after a journey of over an hour. The intestine was reduced, having been left alone till admission, and the abdominal wound sewn up. The thoracic wound was on the right side, parallel to the third rib, beginning close to the border of the sternum. It was four-fifths of an inch long, and no blood escaped from it at the time; it was drained and sutured. There were no signs of cardiac or pulmonary mischief. On the evening of September 13, after doing well for many days, pain and dyspnoea troubled the patient, and hæmorrhage occurred from the thoracic wound, which recurred on the evenings of the 14th and 15th, so that the patient became anæmic. On September 16, Dr. Madelung opened the wound. The right third costal cartilage was cut through close to the sternum. Arterial hæmorrhage was observed above and below the cartilage, about an inch of which was resected. A cavity in the anterior mediastinum, "the size of a goose's egg," was exposed; it was full of clot. An inch of the fourth costal cartilage was resected; in so doing the operator opened the pericardium. Apparently that serous sac had been opened by the stab, and

had speedily closed, the operation breaking down the adhesions which closed it. Much hæmorrhage accompanied the opening of the hæmatomediastinum, the blood gushing from the lowest part of the wound. Dr. Madelung therefore tied the internal mammary artery in the fifth intercostal space, in its continuity, when the hæmorrhage ceased. The cavity was packed with iodoform gauze, and a tampon of the same material was placed over the wound in the pericardium. The patient recovered. Dr. Madelung believed that the abdominal wound did well because no clumsy attempt to reduce the gut had been made by the patient's friends. He insists that, when the internal mammary artery is divided, both ends should be secured, on account of the innumerable anastomoses, especially with the deep epigastric.—*Brit. Med. Jour.*, Sept. 15, 1888.

SENSITIVE DENTINE.—One of the difficulties to be overcome in tooth filling is the occasional extreme sensitiveness of the dentine; and it requires considerable courage on the part of the patient to submit to the necessary cutting. Healthy dentine is endowed with but little sensibility, for if a tooth be accidentally chipped so as to expose a portion of the dentine without opening the pulp chamber, it can at first be touched without giving rise to pain, but after twenty-four hours' exposure to the fluids of the mouth it becomes irritable. Hyperæsthesia of the dentinal fibrils may follow any form of exposure—that due to caries, erosion, or fracture; and when present it varies considerably in intensity, not only in different teeth, but in different parts of the same tooth. Immediately under the enamel, in proximity to the pulp, especially the fibres radiating from the cornua of and just beneath the appreciably softened carious bone, are the situations of greatest sensibility. The two former are explained by anatomical facts. The dentinal fibres end at the periphery by forming a dense network, and open into the so-called inter-globular spaces, which, however, are filled with protoplasm similar to that contained in the lacunæ of bone, the whole forming the granular layer of Tomes, and near the pulp the fibrils are both more numerous and of larger calibre. The deepest portion of the diseased bone is probably most sensitive, because here the calcareous material has been removed, exposing the fibrils, while it has not gone far enough to destroy them. It will readily be understood from this that superficial cavities are often very sensitive; then, as the disease progresses and this portion of the dentine is destroyed, there comes a time when there is but little pain from contact with acrid fluid or solid substances, but acute sensitiveness is again met with as the pulp is approached. Other things being equal, soft teeth, from their relative greater quantity of organic matter, will be more sensitive than hard

teeth, although there are many exceptions to this rule; also the teeth of the young more than those of the aged. The various methods of treatment may be summed up under the following heads: (a) operative measures, (b) desiccation, (c) cauterization, (d) local anæsthesia; and this is probably the order of their efficiency, although combinations are often valuable. (a) Sharp instruments, rapid motion of the engine, and taking advantage of anatomical knowledge by cutting away from the pulp and its cornua and across the line of the fibrils, will suffice in most cases. After the insertion of a temporary plastic filling for a few months, it will generally be found that most of the sensitiveness has disappeared; and this is the best of all treatment if the patient is under constant supervision. (b) In order to get thorough dryness, the rubber dam must be adjusted and the cavity swabbed out repeatedly with cotton wool dipped in CHCl_3 or absolute alcohol, or, better still, a current of hot air passed through the cavity. Chloride of zinc acts partly as a desiccator and partly as an escharotic, but its application is usually very painful, and its use contraindicated when the pulp is near. (c) Carbolic acid, chloride of zinc, nitrate of silver, and caustic soda all have their advocates—carbolic acid, perhaps, being the most general favorite. Arsenious acid left in for a few hours is most efficacious; but, owing to the numerous cases of death of the pulp resulting, is now rarely resorted to. (d) Cocaine alone, or in conjunction with sulphuric ether, although of great use as a local anæsthetic in treating pulps, has not proved of much service for sensitive dentine, as it is not readily absorbed. Other drugs, such as menthol and aconite, are equally disappointing. Dr. Ottolengui's method seems, as far as experience has gone, to give good results. He first dries the cavity with hot air, and sometimes uses carbolic acid as an escharotic, and then anæsthetises the dentine with ether spray. It is maintained that the pain produced is far less than the operation of cutting by any other method. It may be interesting to note the statement that, where teeth are forcibly wedged apart for the purpose of gaining room for filling, the pain of excavating is much diminished, presumably from constriction of the nerve as it enters the apical foramen. Cocaine injection into the gum, as used for extractions, has also been recommended, but has not given encouraging results.—*The Lancet*, Oct. 27, 1888.

SALICYLIC ACID IN MALIGNANT SCARLATINA.—DR. A. SHAKHOVSKY emphatically recommends (*Novosti Terapii*, No. 6, 1888, p. 208) the salicylic treatment of scarlet fever, the recommendation being supported by 125 malignant cases of the disease, with only three deaths. He always employs the following formula: R Acid; salicylic; gr. xv.; aq. distill. fervid., 3ij; syrup. au-

rantior, 5j.; M.S. From a teaspoonful to a tablespoonful every hour during the day time, and every two hours by nights. The solution of the acid is said to be perfect, as well as palatable. In about two or three days the patient's temperature falls from 41°C. down to 38.5° or 38°C. , reaching 36.5°C. about the tenth day of the treatment. To prevent any relapse (of fever and all) the mixture must be administered every two hours for two or three days after the defervescence. Dr. Shakhovsky assures that salicylic acid, when administered after his plan, successfully prevents all complications (such as uræmia, dropsy, diphtheroid anginas, lymphadenitis, etc.), and even rapidly removes them when they are present. The salicylic treatment fails, according to his experience, (1) when it is resorted to too late (later than a fourth day of the disease of a malignant form), and (2) when there are simultaneously present certain severe chronic diseases or serious congenital defects.—*Provincial Medical Journal*, October 1, 1888.

BENZOATED CHLOROFORM.—DR. B. W. RICHARDSON recommends the use of benzoated chloroform as an antiseptic of considerable service in the treatment of foetid wounds. It is made by dissolving three drachms of pure benzoic acid in twelve ounces of chloroform, and filtering if necessary. In a case of foetid ulcer of the lower extremities, after the bandage has been applied, he prescribes a fluid drachm of the solution poured over or near the ulcer, the deodorizing effect being of the best character. He states that the solution is also the most effective that he knows of for removing the factor in troublesome cases of foetid exhalations from the feet. Used like eau de Cologne, he finds it advantageous to rub over the hands at a post-mortem examination, and for similar purposes where a disinfectant is required.—*Asclepiad*, Vol. v, No. 19.

PILOCARPINE IN DEAFNESS.—M. BÖKE stated at the recent Otological Congress at Brussels that he had used pilocarpine in 14 non-selected cases of deafness. The causes of deafness were cerebro-spinal meningitis in 5 cases, a fall on the head in 4 cases, various pathological lesions of the middle ear in 2 cases, drugs (sulphate of quinine, salicylic acid) in 2 cases, and an affection of the tympanum in 1 case. Of the 14 cases 7 were of several years' duration, and 7 of from 3 weeks to 6 months. The quantity of pilocarpine given in each case was from 65 to 560 millig. The duration of the treatment was from 2 to 6 weeks. Some amelioration was obtained in 3 cases, in one of which the deafness was due to cerebro-spinal meningitis. Böke concludes that the results of the pilocarpine treatment are discouraging. ROHRER has used pilocarpine with good results in deafness due to labyrinthine lesions, the hearing increasing from 2 cm. to 2 or 3 metres. He gives 5 millig. internally, three times a day.

SATURDAY, NOVEMBER 17, 1888.

THE MEDICAL EXAMINING BOARD OF
VIRGINIA.

Most of our readers—all who are interested in higher medical education—will be glad to learn that the Medical Society of Virginia, at its recent annual meeting at Norfolk, showed its appreciation of the valuable work done by the Board of Medical Examiners by re-electing the whole Board, with the exception of Dr. Lankford, who resigned (though not in consequence of any objection to him as an efficient member of the Board). At this meeting of the Medical Society of Virginia 180 members were present—the largest attendance in the history of the Society—and the action in regard to the Board of Medical Examiner was unanimous; the Society endorsed without a dissenting voice the policy of the Board of Examiners. It is evident, therefore, that the profession in Virginia appreciates the work done by the Board in the cause of medical education, and the Board now begins a term of four years' work, which we hope will be even richer in good fruit in the future than it has been in the past. The opposition that was expected, and which there was every reason to believe would be shown at the Norfolk meeting, did not appear except in the way of some rather uncomplimentary references to *THE JOURNAL* by a former opponent of the Board. *THE JOURNAL* has no intention of currying favor with any one opposed to higher medical education, especially when the opposition proceeds from personal motives. We are gratified to have received letters from members

of the profession in Virginia saying that the stand taken by *THE JOURNAL* in the case of the Examining Board is appreciated.

To the owners, stockholders, and professors of the colleges that have been and are doing discreditable work we would say: You have been weighed in the balance, and are found wanting. There are but two courses open to you; go on as you have done in the past and are doing now, and some day you will find the seal of disapproval, professional and public, upon your permanently closed doors and empty lecture rooms. The other course is to do better work, and when you do this, you will be as much in favor of medical examining boards as the medical men who are loyal to their profession and thoughtful of the public welfare. There are far too many medical colleges in this country. Every new medical examining board created is a nail in the coffin of some unnecessary, low-class medical college. The colleges that hope to survive must begin the work of reformation now. The time will come when even *State* medical institutions must either place themselves on the side of higher medical education or drop out of existence. Professors in low-class medical colleges may fight boards of examiners, and ask to have *their* students exempted by legislative enactment from the test that will determine whether they are qualified to practice medicine. But they are both in the minority and in the wrong. The mass of the profession is against them, the teachers in the high-class colleges are against them, reason is against them, and the tide of intelligent public opinion is setting against them. Against the right and the majority they cannot hope to win. They must reform or close their doors.

These words are not directed more particularly to one low-class college than another. With the one case in which the teachers of a college declared war against a State Examining Board, and wished *their* students exempted from the State examinations, we have finished, for the present at any rate, since they seem to have seen the error of their ways to a certain extent. But the report of the Virginia Examining Board showed, in a way, that one-half of the colleges in this country are doing bad work—13 out of the 26 colleges whose graduates were examined by the Board. In the editorial in *THE JOURNAL* of September 6 we

gave a list of these 13 colleges, and some facts in regard to them that go to show that they are not doing good work, and why they should not be classed among high-class colleges. We shall await with interest the next annual report of the Virginia Board of Medical Examiners. Before it can appear, however, the colleges have a whole session in which to begin the work of reform. But if they persist in their former course they can expect only the inevitable.

THE HARVEIAN ORATION.

On October 18 DR. P. W. LATHAM delivered the Harveian Oration before the Royal College of Physicians, "to commemorate the benefactors of the College, and to encourage its members to search out the secrets of nature by way of experiment," in accordance with the express wish of Harvey. Dr. Latham points out directions in which further advances are possible, and suggests routes by which these advances may be made; he pictures some of the discoveries that have been made in modern times in matters connected with the circulation, particularly in reference to some of the changes in the blood that may be associated with or productive of disease, thus indicating some of the additions to Harvey's great contribution to scientific medicine.

Dr. Latham calls attention to the colorless corpuscles of the blood, and asks if there is an antagonism or attraction between these white corpuscles and the bacilli. How are the powers, action, and growth of the colorless corpuscles modified by the presence of micro-organisms? What part do the latter play in the production of disease? Is it true that a large part of all health and disease in the world is dependent upon them? These questions, and our inability to answer them, show the degree of importance that must be assigned to the discovery of these bodies, and account for the large amount of interest now manifested in them. Dr. Latham points out some of the facts that are now known regarding these bodies. There is but little doubt that in some disorders these organisms are the causal connexion, the virus of the disease—as in anthrax or splenic fever. In relapsing fever we have a disorder associated with a bacillus, the organism disappearing and reappearing, and the blood of the infected animal being intermittent in its

power of communicating the disease to other animals. We all know how great interest has centred in the bacillus of tuberculosis, and how carefully this micro-organism has been studied for almost nine years. Following upon Koch's discovery of the tubercle bacillus came Metschnikoff's discovery of the antagonism between the cells and bacteria.

Bacilli may not be destroyed by the colorless corpuscles, however, but may live in the blood and tissues of the animal; what changes do they produce in this case? It seems now that certain chemical poisons are produced, capable of destroying life; as the result of albuminous or proteid decomposition or putrefaction certain animal alkaloids are produced, similar in nature and chemical composition to the vegetable alkaloids. Some of these ptomaines, as they are called, are harmless, while others are more or less poisonous. Had Kerner known this nearly seventy years ago he would not have been at a loss to account for the similarity of the effects of sausage poison to those produced by atropine. We need not go into an enumeration of the different ptomaines that have been discovered and described, since those interested in the subject can obtain what information they desire from the recent work on the subject by Dr. Victor C. Vaughan and Dr. Frederick Novy. Suffice it to say that, knowing the operations of the micro-organisms of fermentation and putrefaction outside the body, analogy would seem to show that the micro-organisms inside the body have similar functions, producing effects that we call disease, caused by the action of the body-microbes. Dr. Latham works out this question carefully, and shows on chemical grounds the possibility that such poisonous products may be produced by disintegration of albumen. He shows also that fatigue may produce these products, even without the intervention of micro-organisms, and suggests that under conditions of lowered vitality our bodies are more readily susceptible to bacterial infection—which is in accord with our knowledge of the etiology of disease.

Dr. Latham's interesting and suggestive lecture shows, to a degree, how vast are the uncultivated fields of medicine. "In the midst of all our weaknesses and all our many errors, we are certainly gaining knowledge, and that knowledge tells us, in no doubtful terms, that the fate of man is in his own hands."

HOW TO DRESS AND WALK.

Last Saturday the women of the Physical Culture Club, of Chicago, listened to a "Delsartian" lecture on "How to Dress and Walk," by a woman who is said to be one of the most accomplished Delsartians in the country. Physical culture clubs among women may be undoubtedly productive of much good; and that women should learn how to dress and walk is important; that they do not know how will be universally admitted. The lecturer last Saturday pointed out that women should abandon the corset, but the reasons seem to be more "Delsartian" than physiological. As far as she went in her advice in this matter she did not go wrong. The lecturer's description of the way to walk was, however, both unphysiological and absurd—though Delsartian. The following was the method given, with illustrations by the lecturer:

"If you put your whole weight on the heel instead of the ball of the foot the tendency is to make the back sink, the abdomen protrude, and the chest to draw in. The first thing for persons who wish to walk well and without effort, and who desire good forms and grace of movement, is to learn to step firmly on the ball of the foot. Next they should throw out and lift their chests as high as possible. Nations and individuals who retrograde are marked by retreating chests and shrinking carriage. There is something about developing a full, high condition of the chest that calls into action all the higher feelings of independence and self-respect."

We ask in all seriousness and with alarm: Is society to be infected with this new "fad," in comparison with which the "Grecian bend," now happily relegated to oblivion, was a blessing? Why has nature provided women with heels if these are not to be used in walking? Fashion and the shoemakers have already done enough in the way of deforming the foot, without the intervention of this new absurdity that tells women to step on the balls of the feet, and thus make walking dolls of themselves. Curious, that mankind, the highest of the animal creation, should be the only living creature that stultifies, deforms and mutilates itself for fashion's sake! Imagine a procession of women on a crowded street, each one stepping firmly on the ball of her foot, and then throwing out and lifting the chest! The heel was made to step on, to bear the whole weight of

the body at the beginning of the step; as the body goes forward the weight is transferred to the ball of the foot, from which the spring for the next step is made. Had the Delsartian lecturer advised her audience to walk on their heels only she could not have committed herself to a greater piece of absurdity than that quoted. Putting the weight on the heel does not make the chest "draw in;" and if it makes the back sink and the abdomen protrude no one is the worse for it. Physiologists will certainly be astonished to know that stepping on the ball of the foot will develop the chest and awaken feelings of independence and self-respect. We were not hitherto aware that our moral intellectuality was located in the foot, and that if we trod on our heels we became slavish and lose self-respect. It would seem that a lecturer on physical culture should at least know something of primary school anatomy and physiology.

THE ILLINOIS TRAINING SCHOOL FOR NURSES.

The eighth annual report of the Illinois Training School for Nurses shows that this institution is in an unusually prosperous condition. The school is now located in its new building, which has ample accommodations for 100 nurses. The mortgage upon the old building still remains unpaid, but the board hopes soon to come into possession of the legacy left by Miss Phœbe L. Smith, when it will then be canceled. The founders of the school are making every effort to secure a fund that will enable them to send its nurses to those who cannot afford to pay for them.

In July last the school took charge of all the nursing in the Presbyterian Hospital, there being five floors and fifteen nurses. In Cook County Hospital the school has ten wards, and during the past year has supplied the county institutions with 107 nurses. One hundred and seventy-seven persons have made formal application to enter the school in the last twelve months. Of this number fifty-nine have been received as probationers and thirty-eight accepted after the trial month, the remaining twenty-one having failed for inefficiency. Six nurses were dismissed, one left on account of ill health, and two were married. The average number in the school has been sixty-eight. The June graduating class numbered eighteen. The number of nurses now

in the school is sixty-six, with nine probationers and fifty registered graduates.

In September last the curriculum of study was revised, and the following text-books adopted: "The New Haven Hand-Book on Nursing," supplemented by Clara Weeks' "Text Book on Nursing," Hutchinson's "Anatomy and Physiology," Potter's "Compendium of Materia Medica," and as a reference library the standard works on anatomy, physiology and obstetrics. The students have opportunities for a broad and practical teaching at the bedside of the sick, as the school cares for an average of 500 patients daily. Lectures and classes begin the middle of September, and close the last week in June.

The almost unparalleled growth and success of the institution is due, in great measure, to the efficiency and faithfulness of the superintendent, Miss Hampton.

CANCER OF THE PYLORUS IN A LIVING SKELETON.

The St. Louis *Globe-Democrat* of a recent date contains an account of a case of resection of the cancerous pylorus in a "living skeleton." The patient, Joseph N. Robinson, of New York, has exhibited himself as a "living skeleton" for twenty-eight years, and is now 53 years of age. About six weeks ago he went into the New York Hospital under the care of Dr. William T. Bull, on account of having become so weak that he had to be carried about, and then only with great pain. On account of his extreme emaciation, probably, he would sometimes lie unconscious from morning till night, and during the night would be hysterical and sleepless. His manager had noticed for some time that there was a tumor in the pyloric region, which could be easily felt on account of the extreme emaciation.

At the time of the operation, about three weeks ago, the patient was 6 feet 2 inches tall, had a waist measure of 14 inches, and weighed 72 pounds. The tumor proved to be a stricture of the pylorus, showing some evidence of cancerous growth (?), and "would scarcely admit a lead pencil." Complete resection of the pylorus was performed, an opening made in the anterior wall of the stomach, and the resected end of the duodenum adapted to this opening. Although the operation was long, but little blood was lost,

and the patient's condition was much better than had been expected. He had no fever, and his recovery was remarkably rapid. At the end of two weeks he felt better than he had for many years, and began to be ravenously hungry, but was allowed nothing heavier than peptonized milk and brandy. Since then he has entirely recovered and is gaining rapidly in flesh. He weighed 100 pounds two weeks after the operation.

"When the pathologist examined the stricture removed from Robinson he found an ordinary pin fast in the middle of the tumor. About this, as a center, ulceration had taken place, and the scars of these ulcers had caused the tumor and the stricture. When told of this circumstance Robinson recalled having swallowed the pin thirty years ago while holding it in his mouth."

The account of the case in the *Globe-Democrat*, is very interesting, and written in the usual happy style of the newspaper correspondent. We hope to see a report from a more careful pen.

EDITORIAL NOTES.

SCARLET FEVER at Palmyra, Wisconsin, has caused the schools of that place to be closed.

MALIGNANT DIPHTHERIA, according to recent reports, is prevalent in the neighborhood of Hawthorne, N. J.

HOG CHOLERA IN OHIO.—Local papers state that hog cholera prevails in Hancock Co., Ohio. In Portage township alone more than 6,000 hogs have died of the disease.

A CASE OF COCAINE POISONING has recently occurred in San Francisco. It seems that the sufferer took the drug without medical advice. The man was taken to a hospital, where he recovered.

A CASE OF SMALL-POX IN OMAHA seems to have aroused not only the Board of Health but the whole population of that city, and vigorous measures are being taken to prevent the spread of the disease.

YELLOW FEVER IN FLORIDA.—The yellow fever persistently continues to find new victims in Florida. November 12th thirty new cases were reported in Jacksonville and three deaths, making the whole number of cases reported to date 4511, and the total deaths 388. One new case was reported in Gainesville, Fla.

TRANSPLANTATION OF THE CORNEA.—On October 5 a little girl, aged 4 years, in Norristown, Pa., had the cornea of a rabbit transplanted in her eye. She was discharged from the Hospital on October 31, with favorable prospects for recovery.

THE McDOWELL MEDICAL SOCIETY met in Henderson, Ky., on November 2. About thirty members were present. Several papers were read and discussed. A grand banquet and hop was tendered the Society by the local members at the Barrett House. The Society will meet in Owensboro on May 3, 1889.

A PECULIAR DISEASE.—Bailey Walters, a prominent resident of Osage Township, Parsons Co., Kansas, died recently, in the 57th year of his age, with a peculiar malignant fever which is epidemic in that neighborhood. Within two months Mrs. Walters and two sons have died, and the remaining three members of the family are sick with the same disease. Last week James Smith and Geo. Mayes died, and four of the latter's family are sick with the fever.

CARCINOMATOUS ULCERATION OF THE AORTA was the cause of death on October 15 of a patient upon whom Dr. James Murphy performed gastrostomy for carcinomatous stricture of the œsophagus on September 9, 1887—the patient having lived 402 days. The immediate cause of death was hæmorrhage from the descending aorta, which had been ulcerated into by a carcinomatous mass.

THE "MARITIME MEDICAL NEWS" is the title of a new bimonthly journal printed at Halifax, N. S. The first number, for November, contains an address by Dr. P. R. Inches before the New Brunswick Medical Society, an address on the Nova Scotia medical act by Dr. William McKay, the report of a case of dilatation of the stomach, by Dr. Page, of Truro, and other interesting matter.

THE "UNIVERSITY MEDICAL MAGAZINE," the first two numbers of which (October and November, 1888) have been received, is edited under the auspices of the alumni and faculty of the University of Pennsylvania, and published by A. L. Hummel, of Philadelphia. The numbers at hand are filled with interesting papers, clinical memoranda, etc., and if merit is an indication of future success the *University Medical Magazine* will succeed.

EXTRALITE is the name of a new explosive, said to be twice as powerful as dynamite, and much safer to handle. It cannot be exploded in the open air, nor by concussion. It seems that it must be confined (tamped) and exploded by means of a fuse. Its safety should make it a popular explosive. The French Government is said to have paid one million francs for the right to use it. It is to be manufactured in this country in New Britain, Conn.

AN OPTICAL DELUSION.—The following is from the *Philadelphia Times* in regard to a young woman who has had one of her eyes replaced by a rabbit's eye, as it seems: "Miss Fisher told a reporter for the *Times* that she could see out of the right eye nearly as well as ever, and that she read quite well with it. Closing the right eye and looking with the rabbit eye, she said she could see to move about the room without stumbling over anything, and she could also count her fingers. At the reporter's request she removed her glasses, and then closing her right eye she was able to describe the movement of the reporter's hand, and in other ways show that, while the sight in the 'rabbit' eye is imperfect and limited, she can see with it." Perhaps, however, it was a case of transplantation of the cornea.

GETTING AHEAD OF DISEASE.—DR. P. R. INCHES, in a recent address before the New Brunswick Medical Society, instanced the city of Edinburgh as showing the benefits resulting from the intelligent use of sanitary and preventive measures. In 1862 the population of that city was 170,000, the deaths 4,661. In 1886 the population was 211,400, but the deaths were only 4,149—a fall of death-rate from 26.65 to 19.62 per 1,000; and the change took place mainly in the diseases most influenced by sanitary precautions—the zymotic class. In 1862 that group accounted for 19.73 per cent. of the total deaths, but in 1886 for 8.34 per cent. only, and this change represents a continuous fall in the percentage. In some of the poorer and over-crowded districts of the city there was a decrease of mortality varying from 3.77 to 20.71 per 1,000. Such diminution of mortality implies an immense saving of life, and is attributed by the authorities to relief from over-crowding, to the opening of new streets and breathing places, better water-supply, new drainage, improved plumbing, and to the system of

notification of infectious diseases, and the isolation and removal of the infected, and disinfection of the place.

OBJECT TO A LICENSE TAX.—It seems that the City Council of Salt Lake City have imposed a license tax upon physicians. At a meeting of the Salt Lake Medical Society, held on October 30, the following communication was passed and sent to the City Council :

At a regular meeting of the Salt Lake Medical Society the action of your honorable body relative to licensing the practice of medicine in this city was discussed. The result of this discussion was, that the present committee was appointed to wait upon the City Council and ask for a reconsideration, for the following reasons :

1. That a license imposed upon one of the liberal professions is unusual, and especially out of place as imposed in the medical profession, because physicians, as a rule, attend to the poor of the city in charity, and do a great deal of work without recompense.

2. If the object of the license is to raise the standard of the medical practice, thereby protecting those in the community incapable of judging the merits of a physician as against the illegitimate practice of medicine, we think the ordinance fails to meet such ends for these reasons: The class of medical men known as quacks draw about themselves a following, which pays them enormous fees, so that they are better able to pay a tax than the honest, conscientious, regular medical man. The quack pays his tax, does his business, the community is not protected, and the standard of the medical practice is not raised.

We would add that the medical society is heartily in accord with any movement which will raise the standard of medical practice in this city, and which will exclude those men known as quacks, and to effect this result we would suggest to your honorable body that such methods be adopted as are found in other communities, as the establishment of an examining board to investigate the merits of all wishing to practice medicine, which will grant certificates of recommendation for license—the fee being a nominal sum. We would respectfully ask your consideration of the above, and that your honorable body will repeal the tax which appears so unusual.

SOCIETY PROCEEDINGS.

Medical Society of Virginia.

Nineteenth Annual Session, held at Norfolk, Virginia, Oct 23, 24, and 25, 1888.

TUESDAY, OCTOBER 23—FIRST DAY.

The Nineteenth Annual Session of the Medical Society of Virginia convened in the Hall of the Young Men's Christian Association, Norfolk, Va., Tuesday, October 23, 1888, at 7:30 P.M., THE PRESIDENT, DR. BENJAMIN BLACKFORD, of Lynchburg, Va., in the chair, and Dr. Landon B. Edwards, of Richmond, Va., Recording Secretary. The Hall (capacity about 400 seats) was well filled—a number of ladies and gentlemen not Fellows of the Society being in the audience. About 180 Fellows in all were registered as in attendance during the session—the largest number ever in attendance upon any session of the Society. In addition, Dr. John B. Hamilton, Sup. Surg. Gen. of the U. S. Mar. Hospital Service, of Washington, D. C., and Dr. Milton Josiah Roberts, of New York City, were present as invited guests.

After prayer, DR. HERBERT M. NASH, of Norfolk City, delivered a most cordial *Address of Welcome* on the part of the professions of the "twin cities" of Norfolk and Portsmouth.

DR. WILLIAM T. WALKER, of Lynchburg, was then introduced by the President, and delivered the *Annual Address to the Public and Profession*, announcing as his subject :

MOSES AND OTHER DOCTORS.

Dr. Walker stated that the hygienic laws of Moses have no practically adopted equals to this day. His march of 2,500,000 people for forty years through the arid desert, all the while observing a system of hygiene such as has never been known in the records of time, was marvelous. The most thorough cleanliness in all things was required of each person. Chlorine preparations are among the best germicides known today ; and yet Moses anticipated this latter day discovery by requiring the preservation of meats, etc., by the use of chloride of sodium. He taught how to disinfect buildings after leprosy had infected them, or, if they could not be purified to destroy them by fire. His laws in regard to the marital relation are perfection. If our women were to follow the special laws laid down by Moses for their health, their would be but little need for gynecologists. It is claimed that *preventive medicine* must be the medicine of the future ; but Dr. Walker proves from the records of Moses and those who followed him, that it was the medicine of the past. It is a striking fact in history that, while the other learned nations of

those ancient days had their high grade schools of medical learning, the Jews had none, for they did not need them so long as they observed the laws of Moses. Passing references were made to the medical records of Hippocrates, of Celsus, of Galen, etc., down to the time of the Great Physician, who came not to destroy the laws of Moses, but to fulfil them. Luke, the "beloved physician," was a scholar of the highest culture and a faithful friend to Paul in prison while it was a danger to himself to be such—illustrating that the true doctor does not flee when danger approaches. Touching allusions were made to the faithful doctors of Norfolk of 1855 when the terrible epidemic of yellow fever swept that city. Tributes were likewise paid to those doctors of Jacksonville and other places who, this year, are sacrificing their lives for the safety of the people. Credit is awarded to the late Dr. Crawford W. Long, of Athens, Ga., as the discoverer of modern surgical anæsthesia by ether. A eulogy is likewise passed upon the immortal Dr. J. Marion Sims. References were made to others who have taken up and further perfected the life work of these great men.

SIXTY-NINE NEW FELLOWS.

The committee on nominations recommended the applications of sixty-nine doctors, who were duly elected Fellows of the Society during the session.

WEDNESDAY, OCTOBER 24—SECOND DAY.

THE PRESIDENT called the Society to order at 10 A.M.

The Recording Secretary presented his report, which showed that during the year just ended, thirteen Fellows had died, and two had resigned Fellowship because of removal of residence from Virginia.

The *Executive Committee* (Dr. W. W. Parker, of Richmond, Va., Chairman,) reported that Dr. James Parrish, of Portsmouth, had been duly nominated to the Governor of Virginia for commission to fill the vacancy on the Medical Examining Board of Virginia caused by the resignation of Dr. L. Lankford, now of Norfolk, Va., which nomination was confirmed by the Governor.

The constitution of the Society was so amended as to permit parties—always of the white race understood—to become Fellows of the Society who had secured certificates of satisfactory examination for license to practice in Virginia, whether graduates of medical colleges or not.

DR. THOMAS J. MOORE, of Richmond, presented the report of the committee appointed by the joint committees of the Medical Examining Board of Virginia, and the Medical Society of Virginia, during its last annual session, to petition the Legislature of Virginia to

AMEND THE EXISTING LAW.

The Committee succeeded in securing amendments in the two important particulars as follows:

1. Requiring all applicants for license to practice medicine in Virginia to stand satisfactory examinations before the Medical Examining Board of Virginia *in session*; or

2. In exceptional instances, for sufficient reasons, to be decided upon as such by the President of the Board, applicants may be granted permission to stand examinations before a Committee of three members of the Board—the Committee to hold the examinations *only in a session*, and not individually as formerly.

The special order of business at 11 o'clock of the morning of the second day's session being the "Annual Address of the President," and that hour having arrived, DR. BENJ. BLACKFORD read a well prepared address on *The Progress of Medical Education, and the Importance of the Study of the Physical Sciences in Relation Thereto, during School Life*. This address will be published in the volume of the Society's *Transactions*.

The subject for general discussion was next called for:

ATYPICAL FORMS OF TYPHOID FEVER.

The appointed Leader, DR. WILLIAM C. DABNEY, Professor of Practice of Medicine in the University of Virginia, opened the discussion by reading a paper on the subject. He took the ground that the disease had become distinctly milder of late years, and that the symptoms, such as diarrhœa, eruption, and the *gradual* rise of temperature which were formerly considered characteristic, are now often absent. That these cases are nevertheless cases of genuine typhoid fever, he considered proven by the following well established facts:

- (a) The cases usually present some of the peculiar characteristics of the disease.
- (b) Hæmorrhage from the bowels occasionally occurs in these cases.
- (c) The intestinal lesions characteristic of typhoid fever have been found on post-mortem examination.
- (d) These mild or atypical cases are capable of originating epidemics of typhoid character.

The conclusions arrived at by Dr. Dabney are thus stated:

1. The disease in this country is gradually becoming milder, and symptoms which were formerly thought to be characteristic and almost invariable are now much less frequently present.

2. The diagnosis of the disease is often attended with extreme difficulty, and in the early stages is generally impossible.

3. In those cases which are apparently extremely mild, dangerous symptoms may arise suddenly, and a fatal issue may ensue from errors in diet or other imprudence.

4. In all doubtful cases precautions should be taken to prevent the spread of the infective principle or germ, and to guard the patient against danger from imprudence.

5. The dangers to be especially apprehended in these cases are exhausting diarrhoea, hæmorrhage, and perforation of the bowel.

6. In view of these dangers, patients should be placed upon liquid diet; should be confined to bed; and constipation, when present, should be relieved by enemata, and not by purgatives, even of the mildest character.

DR. JOHN HERBERT CLAIBORNE, of Petersburg, said that the first point is the selection of a common ground upon which contestants may stand. In other words, a mutual but definite understanding of what each may mean by the term typhoid fever. The subject proposed—"Atypical Forms of Typhoid Fever"—supposes, of course, that there are "typical forms." What are these? By the expression *typical* he thinks we all agree that *representation* is meant—and a typical case of typhoid fever is understood to be a representative case. Now, what are the symptoms that *characterize a representative, or typical case*? In its generic or derivative sense, we should say that a typical case of typhoid fever should show at sometime during its course symptoms of stupor, or at least, of dulness or hebetude of mind. There should also be noted a diarrhoea of peculiar form—that there should be a pathognomonic rose-colored eruption on or about the 14th day of the disease—that there should be epistaxis—ordinarily slight. We should say, again, that the fever was self-limited; that it was, perhaps, mildly infectious; that it oftener attacked adolescents; that it had its own recognized microbe; and that above all others necropsy should develop, distinctly and unquestionably infiltration and ulceration of the glands of Peyer. We might add to these general symptoms, slight bronchitis, gurgling in the right iliac fossa, headache, anorexia, tawny flesh of the cheek, and a temperature steadily and progressively rising and subsiding.

The question then arises, how many and which of these symptoms can we eliminate from a *typical* case in order to render it *atypical*? In other words, if typhoid fever be a disease marked by certain pathognomonic symptoms and pathological lesions, how many or what symptoms or lesions can we take out and still leave the disease an entity—a recognizable unit? And, if we are not in danger of multiplying words, are we not in danger of multiplying diseases to the confusion of diagnosis?

There is a fever, a summer and autumnal fever, common to many sections of Virginia which it has become fashionable to note as *typho-malarial fever*—a term that originated during the late war between the States, and for which the late Dr. Woodward of the United States Army was per-

haps responsible. At least he contended that it was a substantive fever, with its own symptoms and its own pathological lesions, and though he subsequently confessed that he was mistaken and recanted at the International Congress of Physicians, in Philadelphia, ten years later, the name has never perished. Wherever there is malaria now—and that seems ubiquitous—there we have typho-malarial fever. Dr. Cutter has published in parallel lines a differential diagnosis between typhoid fever and typho-malarial fever, which throws great light on this subject, and places the latter where, of right it belongs, viz., in the class of *ordinary bilious remittent fever*. Any fever, or any disease, may assume under certain unsanitary or depressing influences, a typhoidal character; but that does not constitute the peculiar intestinal, enteric, or typhoid fever to which we were introduced in our student days by Lewis, or Gerhard, or Wood; nor can we think that there is any blending of type in the two forms—any swapping or coincident or concurrent cultivation of the microbes peculiar to each. And in the treatment of these so-called typho-malarial fevers, the early, honest, and judicious administration of quinine will ordinarily cut short the attacks. He has rarely seen one of these hybrid fevers run into a typhoid condition unless there was delay in the exhibition of the great antiperiodic, or it were given in pills or capsules and, per consequence, undigested, or unless there was present some real or imagined idiosyncrasy preventing the use of this agent. When the fever persists in spite of this treatment you may suspect the correctness of your diagnosis, or know that there is some local cause of irritation apart from malaria. In his experience, a mild mercurial every night, guarded or not with some preparation of opium, according to the condition of the bowels, and from twenty to thirty grains of quinia at the period of remission, with fifteen grains of antifebrin, or thirty grains of antipyrin during the period of exacerbation, in three equally divided doses, will ordinarily cut short the fever in from three to eight days.

DR. W. G. ROGERS, of Charlottesville, presented a paper tending to strengthen the evidence already existing that *drinking water polluted by sewage* is a most fruitful source of typhoid fever. Previous to the establishment of the Charlottesville Water-works by which pure mountain water is now supplied to the city there was much typhoid fever. Then his place was supplied with well water contaminated by surface drainage, etc. But now typhoid fever is comparatively rare, and the cause of the few cases that are occurring is traceable to the fact that the parties use well water. Of the total of fifteen cases of this disease seen by him within the past two months, all were users of well water, which wells were plainly the receptacles of contaminated surface drainage. As illustrative of *atypical* forms of typhoid fever seen

by him, he mentions one with very slow pulse in a boy 10 years old. He also had all the usual signs and symptoms of typhoid fever except fever itself. His pulse varied from 48 to 50 for three weeks; and during the same period of depressed pulse, especially during the evenings, his temperature was subnormal—varying from 96° to 98° F. He reported also two slow-pulse cases, occurring in sisters, aged 12 and 14 years, respectively, sick at the same time; but the other prominent symptoms of typhoid fever were wanting, and the disease was definitely diagnosed simply by the fact that four typical cases were present in the same house at the same time—all due to the one cause of drinking contaminated well water. One slowly improved and was convalescent in two months; the other sister died from asthenia at the end of the fourth week. Autopsy revealed deep ulcers of the ileum, but no perforations. These girls developed a disposition to sing throughout the disease—a disposition not before developed. He reported another case, in a girl 17 years old, in which the average morning temperature (106° F.) was higher than the evening (104° F.). She apparently passed into a comatose stage several times, from which she was relieved by stimulants—an odd fact in itself. He also reported a uræmic case relieved by jaborandi.

DR. THOMAS J. MOORE, of Richmond, asked Dr. Dabney if he recognized such a fever as typho-malarial? The reply was, Yes, but he thought it was the product of two diseases in the system at the same time.

DR. S. K. JACKSON, of Norfolk, read a paper relating to some points in the

TREATMENT OF TYPHOID FEVER BY THE SALTS OF AMMONIUM.

(See THE JOURNAL of Nov. 24.)

DR. LEWIS G. PEDIGO, of Roanoke, stated that he has found great difficulty in diagnosing some cases of fever recently occurring in his section; but they were finally recognized as atypical forms of typhoid fever—the peculiarity consisting chiefly in the high temperature from the very commencement of the attack. It was the form of cardiac typhoid fever spoken of in some of the books, in which there was early failure of the heart. There was great difficulty in controlling the temperature throughout the attack, especially during the latter stages, and the disease ran a very rapid and generally fatal course. The difficulty of differential diagnosis was chiefly between cardiac typhoid fever and a type of continued malarial fever occurring in some localities, mostly about the mountain regions. Even in these malarial types, as also in typhoid fever, quinia does harm. It certainly should not be given in larger quantities than about 5 grs. in twenty-four hours. From the onset to the decadence of the fever, muriatic acid should be given in repeated doses each

day. Antipyrin is also useful, and when he associates the acid with antipyrin, he thinks he has made the best therapeutic combination.

DR. JOHN H. NEFF, of Harrisburg, said that he could confirm what had been so well expressed by Dr. Dabney, though his fields of observation were different. During the past summer he has seen many cases of atypical typhoid fever like those described by Dr. Dabney. There was some difference of opinion expressed in his vicinity as to the nature of these cases—one observer holding that they were malarial. He did not believe there was a malarial miasm in Harrisburg. Early recognition of these cases was very important. Treatment consisted in absolute rest and diet; individualizing each case. He thought typho-malarial fever a misnomer. We might as well say pneumonia-malarial, dysentery-malarial, etc. Environment modified all diseases. He could not endorse Dr. Jackson's ammonia treatment, and did not believe in any specific for the disease.

In answer to a question by Dr. S. K. Jackson, Dr. Neff stated that he had been using the nitrate of ammonia treatment, etc., advocated by Dr. Jackson, for a few months—sufficiently long to persuade him not to depend upon it in the future.

THURSDAY—EVENING SESSION.

DR. C. T. LEWIS, of Clifton Forge, read a paper devoted principally to a

NEW TREATMENT OF TYPHOID FEVER.

He thinks if he can keep the secretion of bile anywhere near its normal quantity and condition, the disease will run a mild and favorable course, because the bile will destroy, or prevent the germs of typhoid fever from finding lodgment in the intestinal canal, or will remove or destroy them if reached. Mercury in some form is about the best and the most commonly used cholagogue. Mercuric chloride is especially recommended on the ground that it neutralizes the toxic product of the disease germs, without destroying the animals themselves, and acts most decidedly upon the liver as a cholagogue. The bile flows into the bowel and acts as a germicide and antiseptic. But after awhile, the continuous use of mercury brings out its own poisonous effects upon the human system, depressing especially the nervous forces, so as finally to bring about a typhoidal condition. It may even cause diphtheritic ulcerations of the intestines, upon which podophyllin, rhubarb, jalap, euonymin, etc., produce a uniform bile secretion, but they irritate the bowels—they are purgatives as well as cholagogues. Ox-bile—theoretically suggested as the correct drug—has been practically tried, but failed to accomplish what was wanted of it. After careful consideration of all the facts, Dr. Lewis now adopts the following plan of treatment: At intervals of two

hours give three doses, but not more, of a powder composed of 2 grs. of calomel and 1 of rhubarb. After this, throughout the whole course of the disease, night and day, give 10 drops of dilute nitro-muriatic acid in a wine-glass of water every two hours. Also give a quarter-glass of fresh milk every three hours, night and day. If the acid and milk come at the same hour, give the acid first, as it gets out of the stomach sooner than the milk. If the patient becomes restless at night, give 2 grains of Dover's powder every two hours, beginning about 2 o'clock in the afternoon, until four doses, and no more, are administered. If the fever rises above 103° bathe the shoulders, upper part of the chest, neck and arms, in cold water every twenty minutes, with a basin of cold water by each side of the patient for his hands to play in; and cloths wet with the same cold water are laid around the neck and on the bowels. The result of this plan is that of 180 cases so treated by Dr. Lewis, only four deaths have occurred, and these deaths were the results of preventable causes by the patients themselves. Be careful not to allow solid food until the patient is well convalescent.

DR. ALBAN S. PAYNE, of Markham, totally differed with Dr. Lewis. The old treatment of Dr. George B. Wood was the best. If Peyer's patches were ulcerated, nitro-muriatic acid would do them injury as an irritant in such a fever.

DR. GEORGE T. WALKER, of Vinton, asked if it was a sufficient length of time to allow two days after the fever leaves before letting the patient take any solid food? Dr. Lewis replied that two days was ordinarily long enough. Then he begins by giving a small Irish potato and a little light bread.

DR. WM. W. PARKER, of Richmond, gives a little chicken soup as soon as possible. It is easily digested and is nutritious, and is not irritant to the inflamed ileo-cæcal region of the bowels.

DR. GEORGE E. WILEY, of Abingdon, asked Dr. Lewis if he ever gave any antipyretics during the course of the fever? Dr. Lewis answered that he did not, except the cold water baths, to which he had referred.

DR. J. H. NEFF, of Harrisonburg, said that he had no faith in any routine treatment of typhoid fever. Early diagnosis is most important. In many cases, absolute rest, both mental and physical, absolute diet, proper surroundings, with good nursing, etc., will lead to recovery. Each case must be individualized and treated according to its symptoms. Some patients cannot take milk. In such cases, he gives chicken and beef soup. Antipyrin, antifebrin, quinine, etc., often ameliorate the symptoms, according to his experience. Morphia often acts well in inducing sleep, easing pain and lowering temperature. Observation shows that quinine is still a good anti-

pyretic—especially in the afternoon—and in many cases does not irritate the stomach, or depress the system, like antipyrin and antifebrin. Opium is often also a splendid antipyretic. But sponging the body with cold water, often repeated, allows us generally to dispense with antipyretics. Aperients are not indicated in any stage; he relies upon enemata to relieve constipation. The mortality of this disease is greatest between the ages of 20 and 30 years. When hæmorrhage from the bowels occurs, he gives opium and enjoins perfect rest.

DR. HENRY M. PATTERSON, of Staunton, spoke of the atypical form of typhoid fever, which starts off with *high* fever and headache. In such cases, we must give some such remedy as antipyrin. Quinine also acts well in these cases. If, however, the sudden onset of high fever and headache spoken of is followed by a chill, the case is not one of typhoid fever, but is a continued fever of another kind. In regular or typical cases of typhoid fever, he has had good effects from aconite as an antipyretic.

DR. WILLIAM L. ROBINSON, of Danville, stated that typhoid fever varied in different sections, being modified by malaria and hygienic surroundings. An uncomplicated case of typhoid fever commencing with general malaise, moderate fever, dry tongue, quick, corded pulse, gradually increasing temperature, reaching its acme at the end of the second or third week, subsultus, tympanites, tenderness in the right iliac region, hot dry skin, delirium, etc., requires conservative management, such as moderate quantities of liquid diet, avoiding that excess which fails of digestion, and produces fermentation and diarrhoea. Turpentine is a diffusive stimulant and antiferment, as is carbolic acid, in connection with tincture of iodine. High temperature produces changes in the blood and parenchymatous degenerations, which weaken the muscular power of the heart. Antipyrin in moderate doses quiets the nervous system, reduces temperature and does much less harm than continued high temperature. The rectal use of digitalis, opium and whisky well sustains the flagging circulation. The use of alcohol in fevers, as recommended by Dr. Flint, in his paper before the International Medical Congress, he fully endorses. He believed in guarding the stomach and guiding the patient through the attack. He could not concur with Dr. Lewis in the use of ten drops of nitro-muriatic acid every two hours, and a quarter of a glass of milk, because it would, in such quantities, produce irritation of the alimentary canal and coagulate the milk, and cause fermentation and gas.

In reply to the criticism, he stated that while nitro-muriatic acid in proper proportions, aided digestion of milk, yet, in the quantities suggested by Dr. Lewis, it would produce results first claimed. He stated further, that the patholog-

ical condition of the alimentary canal in typhoid fever implied ulcerative and inflammatory conditions, and it was a well known fact that, even in ordinary ulceration of the stomach, an absolute alkaline condition offered the only redress. He therefore concluded that such an amount of acid as was suggested, was irrational. He urged upon the Society to be slow in accepting the statistics of a limited number of cases as proof of the efficacy of any line of treatment, for the epidemic might have been, and most probably was, of a mild type, and needed little treatment of any kind. He believed that ten drops of nitromuriatic acid every two hours, and a quarter glass of sweet milk, would, if persistently used, put any healthy man in bed in forty-eight hours. He had not heard the paper and discussion, prior to his coming in the room, but he was convinced that that form of fever which presented excessive high temperature in the beginning, clean tongue, a pulse not exceeding 100 a minute, good digestion, no diarrhoea or tympanites, etc., would be materially modified by quinine, because malaria was the complication.

DR. HUGH T. NELSON, of Charlottesville, said that he had received his medical education in Piedmont, Virginia. At that time typhoid fever was considered *the fever* of the section; and upon settling in a section of the State, in which malarial diseases were of frequent occurrence, he frequently thought he saw cases of typhoid or enteric fever; and subsequently, upon removing to Charlottesville, he had seen a good many cases of continued fever, some of which resembled the cases he had seen in the Lower Country; while other cases differed from it in many particulars. The important point was to decide in any given case of continued fever, whether or not he had present a disease, which had its starting point in *irritation*, and subsequent inflammation of the intestinal glands. Unless this point could be determined, there was no certainty that we had typhoid fever. Hæmorrhage from the bowels occurred by passing congestion in cases of fever in which, though the interval glands showed congestion also, there was no ulceration, and no actual acute inflammatory condition. In another class of continued fever, the hæmorrhage, when occurring, occurred by an acute inflammatory process, which destroyed the previously much enlarged intestinal glands and the blood-vessels supplying them—the general mucous surface of the bowel remaining intact, or else only showing slight *active* congestion, evidently secondary to that occurring in the glands. He believed this to be the characteristic form of hæmorrhage in typhoid fever. These were certainly *typical* cases of this typhoid or enteric fever; but many cases are no doubt put in the category of typhoid fever which do not properly belong there. The importance of a differential

diagnosis cannot be overestimated in the study of continued fevers, so that proper treatment may be instituted.

DR. LEWIS G. PEDIGO, of Roanoke, objected to certain doctrines laid down by Dr. Robinson. The great effort now being made to arrive at a specific treatment of typhoid fever will finally bring about a tangible result. The trend of medical thought and medical practice in this connection is toward the chlorine group. He believes that the proper use of some member of this group of germicides will ultimately furnish the key to the solution of the great problem. He criticized Dr. Robinson's objection to the acid treatment by suggesting that muriatic acid as an important agent in the process of digestion; and so far from aggravating the already existing irritation of the alimentary canal, it has a tendency to relieve such irritation by *preventing* fermentation, which produces the irritating agents.

DR. C. T. LEWIS does not believe that nitric acid prevents putrefaction.

DR. L. B. ANDERSON, of Norfolk, stated that all the speakers had seemed to assume that bacteria are pathological factors, whereas they never have been, and never can be such. They are of vegetable and not animal origin. He has never seen any signs of life in any vegetable or animal matter, or laudable pus from anthrax, furuncle, abscess, or gonorrhoea, until it has been exposed to the air under suitable temperature—until, in short, fermentation or putrefaction had developed. Bacteria, therefore, are a product, and not a cause of fermentation or putrefaction. We should rather look upon bacteria as the best friends the doctor has for preserving health.

(To be concluded.)

Medical Society of the District of Columbia.

Stated Meeting May 23, 1888.

CHARLES E. HAGNER, M.D., VICE-PRESIDENT,
IN THE CHAIR.

DR. G. WYTHIE COOK presented the specimen and read the history of a case of

CANCER OF THE INTESTINE.

(See page 699).

DR. BUSEY: The specimen presented by Dr. Cook is very interesting and presents unusual conditions for a malignant growth. It looked like a cyst that had sprung from the uterus. He moved its reference to the Microscopical Committee. Carried.

DR. H. L. E. JOHNSON presented the specimen and read the history of a case of

FIBROID POLYPUS OF THE UTERUS.

History.—Mrs. T., white, æt. 33, four children

and no miscarriage. Last child delivered by me two and a half years ago; labor normal. Has always been healthy. Menses normal, lasting seven or eight days. Has complained of no special symptom till about five months ago, when she noticed an excessive leucorrhœal discharge, which increased steadily in amount and became more offensive till the odor could be noticed anywhere about the house. She had weakness, nervousness and backache.

Examination showed vagina filled and distended with a decomposing soft mass about the size of a foetal head, breaking down under the least pressure. Its point of attachment could not at the time be made out. After removing the vaginal portion by forceps the vaginal walls were found to be covered here and there by large ulcerated patches caused by pressure, and the cervix was covered with granulations which would bleed on the slightest pressure. It looked like a malignant carcinomatous condition. The sound passed 7 inches into the uterus. The mass was found to be attached principally at fundus uteri, and at points in cervical canal.

On May 7 the patient was anesthetized by Dr. D. K. Shute, and being assisted by Dr. James T. Young, I dilated the cervix (cervical attachment having been separated before) and passed the ecraseur as far as the fundus and around the growth separating it. Applied tincture of iodine (Churchill) to uterine cavity. No hæmorrhage followed; nor pains, nor soreness. Required no further treatment. Patient up on eighth day, well. Vagina and uterus normal. It is interesting and peculiar, as there was no hæmorrhage nor menorrhagia, and that so large a decomposed mass produced no septic symptoms. After separating the cervical attachment of the growth septic symptoms developed from absorption through denuded healthy surfaces. These were relieved by antiseptic injections and the application of a saturated solution of chromic acid.

DR. REYBURN: To what did Dr. Johnson attribute the septic symptoms after operative interference?

DR. JOHNSON: It resulted from the breaking down of the attachments to the cervix.

DR. SAMUEL C. BUSEY read a paper on

NEURALGIA OF THE LINGUAL BRANCH OF THE RIGHT TRI-FACIAL NERVE.

(See page 697).

DR. J. TABER JOHNSON: Was electricity tried in Dr. Busey's case?

DR. BUSEY: It was suggested, but the patient was unwilling to try it.

DR. A. F. A. KING: The attacks started after reading aloud for some time. The woman was not accustomed to it and this would be an unusual use of the tongue for one 57 years old. This evidence was corroborated by the fact that talking

and masticating produced pain. What remedies had been used? Was she anæmic?

DR. BUSEY: The patient stated she had taken large quantities of quinia and other drugs; had been salivated; her face and jaw had been blistered; anodynes of every description had been used locally and hypodermatically; and she had grown worse all the time. She was not anæmic, but in good health. Mastication was interrupted, and she had to be very particular with her dietary. She could not eat bread and potatoes. After reading aloud for three or four weeks the first attack began and the paroxysms recurred at intervals until spring. These attacks recurred annually for seven years, at the beginning of winter. The summer of 1887 was spent in the North; she came here in November, and soon after went into a greenhouse and the paroxysm suddenly came on. She had derived comparative ease from small doses of morphia, but was not cured.

DR. SCHLEEFER: Had suffered from tri-facial neuralgia caused by a carious tooth. He found that if he neglected his food the exacerbations were worse and the paroxysms lasted longer. He had advised systematic feeding and keeping the stomach full. This seemed to assist the remedies and have a beneficial effect. He had found the same experience with the temperature; they appeared in October and disappeared with the coming of spring. No two cases of neuralgia are alike. He derived great benefit from 2 grs. of opium, 10 grs. of quinia and 2 ozs. of whisky.

DR. REYBURN: Had had a patient under his care for neuralgia of the scalp, caused by cutting the hair very short. He was benefited but was subject to attacks afterwards. He was relieved by potassium iodide and cod liver oil. Had no evidence of syphilis. Dr. Busey's case might have been benefited by surgical treatment.

DR. J. FORD THOMPSON: In all such cases where medical treatment fails it is well to try surgical. To treat neuralgia of the lingual nerve surgically can only be practiced on the anterior part of the tongue where it is very superficial. The nerve might be cut on the side of the tongue and the neuralgia relieved, but such a procedure would be impracticable posteriorly, where the nerve is very deep. He then gave the histories of two very interesting cases of neuralgia of the tri-facial nerve, where operation had afforded some relief. In one he had cut the nerve at its exit from the foramen rotundum, and he had had relief for a year, but now wanted to be operated on again. But Dr. Thompson did not know what to operate on. He had tried electricity, but the patient was made very much worse. If he could locate a painful nerve he would operate. This is about the history of a great many cases of tri-facial neuralgia. He could only find recorded two successful operations.

DR. SOTHOROX called attention to the value of

antipyrin in the treatment of neuralgia. He had treated several cases successfully with it in combination with morphia and quinia.

DR. HOWARD mentioned a case recorded in Sir Charles Bell's Memoirs. A child was treated for neuralgia with the usual methods then in vogue, and given up. Bell found green matter running out of its mouth, and found an abscess in front of the ganglion of Gasser.

DR. BUSEY: The history would exclude any local cause. He had considered the propriety of the operation referred to by Dr. Thompson, but had concluded it was impracticable, because these and, perhaps, other nerves were involved. He thought it probable that a better result might be obtained if the treatment tried during the past winter could be begun early and faithfully carried out. He had not supposed that the general subject of facial neuralgia would have been discussed, but had hoped that the peculiarities of the reported case would have commanded the attention of the members.

DOMESTIC CORRESPONDENCE.

LETTER FROM NEW YORK.

(FROM OUR OWN CORRESPONDENT.)

Neurasthenia; its Differentiation and Treatment.

At the first meeting of the season of the Section on Practice of the Academy of Medicine there was an animated discussion on the much vexed subject of neurasthenia, which was introduced by Dr. Landon Carter Gray in an elaborate paper entitled:

"Neurasthenia; Its Differentiation and Treatment." Dr. Gray first directed attention to the fact that functional nervous diseases are largely disregarded by the general practitioner because of the modern development of the study of them, although the need of their proper classification was widely felt, especially by neurological specialists. For this reason it was that the writings of the late Dr. Geo. M. Beard had had such a success in Germany. Dr. Gray did not believe that properly so-called neurasthenia was as prevalent as the followers of Beard would have us believe. He stated that, in his opinion, there were three forms of neurasthenia: the reflex, the lithæmic and the simple. The reflex form was due to vicious habits and reflexes from non-nervous organs, the lithæmic was due to the condition known as lithæmia, and the simple form was that in which there was true nervous prostration. The points of differential diagnosis of these various forms were then dwelt upon. But, he said, neurasthenia was also to be differentiated from a number of nervous diseases, especially the early stages of the latter, such as the morbid fears (for which Dr. Gray suggested

the name of functional insanity), and which really belonged to the insane diseases and were often associated with them; melancholia, especially the mild cases, in which suicide was often committed; the early stages of mild chronic forms of insanity; neurotic conditions in which the individual is subject to migraine, hysteria, angina pectoris or anginoid attacks; the early stages of general paresis of the insane or of locomotor ataxia; and a peculiar disease described a year ago by Dr. Hughes Bennett, and called by him muscular hypertonicity, in which the symptoms are those of weakness and exaggerated reflexes of the lower extremities.

The prognosis of these different forms was variable, depending upon the severity of the reflex cause when present, and the possibility of thorough treatment. The treatment of the reflex form was the removal of the cause, if possible. The lithæmic form was to be treated by moderate laxatives, dilute nitro-muriatic acid and, if the nervous symptoms were severe, by rest. In any event, rest was a most important adjuvant, and should be proportioned to the needs of each particular case; it being better to have rather too much of it than too little. The diet should be regulated to a moderate degree by the entire withdrawal of either starchy or nitrogenous material for a short time, and then by the cutting down of the starchy material permanently by at least 50 per cent. In hot weather it was sometimes advisable to cut off the nitrogenous material for several weeks; and a complete change of air was often of the greatest benefit.

In the true cases of neurasthenia the best treatment was that advocated by Dr. Weir Mitchell, of rest, forced alimentation, massage and Faradism. Large doses of iron and malt extract should also be given in this treatment, the great difficulty with which was, however, that patients are apt to be disappointed at the loss of their muscular strength upon first getting out of bed. It should be explained to them that this would gradually return; but great care was necessary with many patients at this period to prevent them from losing the flesh and red blood that had been gained. Galvanism was an agent of great value in all these forms of neurasthenia, and it should be used as early as possible, except when the case is to be put to bed. It should be applied by means of large sponges, one at the nape of the neck and the other on the dorsal spine, 5 to 15 milliampères of electricity being used, and the sittings continued every day for from three to five minutes. Massage was an uncertain remedy, often irritating the patient, and was only to be used in connection with the rest treatment mentioned.

Dr. W. R. Birdsall thought that we must unquestionably admit a neurasthenic element in disease; yet at the same time, when we attempted to apply it to a group of symptoms, we found that

it often failed. In many individuals the nervous tendencies predominated as a result of hereditary influence, and it seemed to him that the great danger was in assuming that we had a congenital neurasthenic condition, when the symptoms were in reality due to local causes or merely temporary conditions. The class of cases which Dr. Gray called the lithæmic would probably comprise the greater number of these, and it was important that they should not be treated on the basis of an unstable or defective hereditary nervous system. If we were to use the term neurasthenia at all, then, he thought we should confine it to the class of individuals who suffer from inherited defective nervous systems, and with the proviso that it was understood to comprise a group of symptoms which might belong to various conditions.

Dr. Gray had stated, he went on to say, that in the class of reflex cases all that was necessary to do was to remove the cause. There was often, however, an acquired condition, the result of reflex irritation, in which the whole nervous system was at fault. The removal of a local cause, whether about the eye, the nasal cavity, or elsewhere, was not always sufficient. In many cases we were still obliged to treat the individual for other neurasthenic symptoms cropping out in different forms.

In lithæmic cases the question of rest or of exertion for the patient was one which he thought must be specially determined in each individual case. In many instances increased activity of a kind entirely different from that to which the patient had been accustomed constituted the most satisfactory means of treatment; and he knew of nothing so good as moderate mountain climbing with a pleasant companion, especially if there were any hypochondriacal elements in the case.

Dr. Wm. H. Thomson said that the term neurasthenia was, no doubt, a very impressive one to use sometimes to patients, but otherwise he abominated it. It ought to be placed, he thought, on the same level as tonic, a word that led to more bad practice than any other in medicine, since remedies which acted in all sorts of different ways were all called tonics. When a patient came to him affected with nervous debility without appreciable organic disease, he said he always put to himself the question whether the individual were not suffering from one of four causes, viz.: virtual starvation; over-strain; some unnatural drain on the system; self-poisoning. Those who were the subjects of virtual starvation (usually females), it would be found, ate no breakfast to speak of, and probably took for their other meals principally tea, bread and sweets. They did not get sufficient nourishment to maintain their respiration and circulation; and the rest cure was therefore the best for them. In the second class rest and food were also required, and oftentimes a change of surroundings. In the third class the

drain, whatever it was, should be checked if it could, and the patient would then get well. The fourth class, that of self-poisoning, was the most common of all, and it was well illustrated by a case that had recently been under his care. A gentleman came to him suffering from cloudy mind in the daytime and insomnia at night, and he was completely relieved by means of bismuth, columbo and naphthalin. Another similar case was also successfully treated with intestinal antiseptics.

It was only very recently, Dr. Thomson continued, that, after paying special attention to various divisions of the organism in turn, we are coming back to that old part of the body that our forefathers used to regard as of so much importance, the bowels. At all times fermentations were going on in the intestines, and at the best moments of our lives putrid ptomaines were going into the kidneys, the liver, and other organs. The trouble with such patients as he was now speaking of was that they were suffering from prolonged self-poisoning, resulting from a deficiency of the natural antiseptics of the intestines, viz.: the secretions. This was the lithæmic neurasthenia of Dr. Gray. Having referred to the quality of the pulse and the character of the urine, which served as useful guides, he said that he had faith in only one real cure, and that was tent-life in the woods.

Dr. A. Jacobi said that of late it had been the tendency in medicine to get rid as far as possible of all names given to symptoms merely, and neurasthenia was of this class. We could speak of it only as a symptom, and it was a symptom common to so many conditions that the sooner it was abandoned the better. It was not simply weakness alone; we had been told that it was a chronic malnutrition of the nervous centres, due either to various adventitious causes or to an hereditary tendency. But congenital neurasthenia did not exist alone. With it was associated weakness of the circulation and the whole constitution. In every case of so-called neurasthenia, then, it should be our endeavor to make a diagnosis, if possible, of the original condition that gave rise to the symptoms met with.

Dr. A. D. Rockwell said that although unprepared to discuss the question at length, he could not refrain from the statement that he believed in the existence, just as he did in that of malaria. The term was, with limitations, a valuable one; although he thought it had been very much abused. The most important point of differentiation was between primary nervous exhaustion and lithæmia.

Dr. S. Baruch said that he was convinced that there was a complex of symptoms which was best designated by the term neurasthenia. In its treatment the principal indication was to prevent tissue change, and there was perhaps no better

method of securing this than hydro-therapy. Many of his patients suffering from this trouble he directed to take a cold plunge-bath every morning; care being taken that prompt reaction followed. He still believed in the term tonic also, and he thought the cold plunge one of the most valuable tonics that we had.

Dr. E. D. Fisher thought the word neurasthenia would be a very convenient one to retain until our knowledge of nervous diseases had become more complete than it was at present. The principal objection to its use was the danger of mistaking for the condition it implied some of the grave organic diseases, especially in the incipient stage; and it was necessary, therefore, that we should be on our guard in this respect. As regards the treatment of neurasthenia, since this condition represented merely functional disturbances, so far as we knew, uniformity was impossible, and each case must be handled according to its individual circumstances.

In closing the discussion Dr. Gray said that one of his objects in writing the paper was to elicit such an expression of opinion from various observers as had now been given. On the whole, it seemed to him that there was an immaterial difference between his own standpoint and that of those who objected to the term neurasthenia. There were certainly many symptoms not of organic origin which we could not classify without resorting to some such expression. It was, therefore, of practical service to retain it, and the subdivision into the three classes which he had indicated seemed to him a convenient one. In the future such advances would no doubt be made that many points which were now obscure would be cleared up, and many of our views would accordingly be modified.

P. B. P.

Cataract Extraction.

Dear Sir:—I read with great interest the article on "Cataract Extraction, etc.," by Julian J. Chisholm, M.D., in *THE JOURNAL* of November 3, 1888. I think Dr. Chisholm is correct in reducing restraints put on patients after the extraction of cataract. I have been an advocate of such a measure, as not putting the patients to bed afterwards, or if at all for a few hours only, for some years. Since my connection with the University of Louisville I have operated on, in the amphitheatre there, 40 or 45 cases of senile cataract. These patients have each walked or rode from five blocks to five miles immediately after the operation, and I have to record the first case in which any serious inflammation has followed, in the person of a man over 80 years old, who removed his bandage the second morning and took a walk. I believe, with Dr. Chisholm, that with less restriction the eye does fully as well and the patient's general condition is left much better.

I regret though to see Dr. Chisholm apologizing for, or rather trying to account for his average of success, by saying, in reply to Dr. Knapp, that his assistant, "Dr. Belt has explained in his paper how these cases were failures in seeing, even when no inflammatory complication had arisen during the after-treatment of the cases; and how an ophthalmoscopic examination showed glaucoma, nerve atrophy and choroidal patches."

Is it customary to operate on such cases? Is it not nearly as possible to make such a diagnosis before the extraction of the cataract as afterwards? As the saying goes, "What is the matter with the candle test of the visual field? Let us show mercy, and consideration for the comfort of those who must submit to our dictation," by dictating that an operation is not advisable under such conditions as no vision will result. You cannot have a disease of the front of the eye which will shut out quick perception of light if the retina, choroid and optic nerve are sound. I never extract or needle a cataract without making the candle test of the visual field. Dr. Chisholm will find in the book commonly used for recording cases of cataract extractions a place for such a record, marked "visual field."

Yours,

W. CHEATHAM, M.D.

303 Chestnut St., Louisville, Ky., Nov. 7, 1888.

Sour Milk and Buttermilk in the Prevention and Treatment of Diphtheria.

Dear Sir:—The quoted article on "Diphtheria in Cats," in a recent issue of *THE JOURNAL*, reminds me of a case of this disease occurring in a favorite Maltese cat of mine many years ago, and for the relief of which I ordered *sour* milk and buttermilk, which she eagerly took and speedily recovered. These were exhibited as comprising the essential nutritive and remedial properties combined in an acceptable form, and to satisfy the instinctive desire for acidulous substances existing in diphtheria with kindred diseases. The milk is most nourishing and partly predigested, while the lactic acid therein, to which they owe their medicinal power, is an active digestive, depurant, refrigerant, antiscorbutic, antiphlogistic, antiseptic and febrifuge, solvent of the fibro-plastic membranous exudate, and general resolvent of this disease with collateral maladies. They are hence generally applicable in the preventive and curative treatment of scorbutic, malarial, inflammatory, infectious, contagious and pernicious diseases, local and constitutional, both in the inferior animals and human beings. Therefore, if people would drink sour milk and buttermilk, sweetened if desired, and give them to dependent children and the lower animals, instead of throwing them away as worthless, thus wasting a valuable nutritive and medicament, they would protect themselves and subjects largely against and

relieve some of the most pestilential and virulent diseases known, as well as many of the minor ailments of life. Alone or in conjunction with the mineral and vegetal acids, and other suitable nourishment and remedies as specially indicated, I have exhibited them for many years and can fully testify to their superior value as nutrient, preventive and resolvent agents in such maladies. Sour milk and buttermilk thus act both as valuable, agreeable food and medicine that can be used *ad libitum*, besides being cheap, abundant and convenient. Each should be taken frequently as an effective digestive, antalkaline, and prophylactic to neutralize the superalkalinity of blood and system as often occurring, and to ward off or relieve diphtheria, scorbutic, inflammatory and pestilential maladies of every grade and character, in cats, dogs, pigs, and other inferior animals, in common with mankind.

GEORGE J. ZIEGLER, M.D.

November 11, 1888.

BOOK REVIEWS.

THE LIFE INSURANCE EXAMINER. A Practical Treatise upon Medical Examinations for Life Insurance. By CHARLES F. STILLMAN, M.S., M.D., Medical Examiner for the Mutual Life Insurance Company; Examining Surgeon of the Travelers Insurance Company of Hartford, etc., 8vo, pp. 186, 16, viii. New York: The Spectator Company. 1888. Chicago: W. T. Keener.

The medical examiner for life insurance occupies an important position; a careless or incomplete examination will generally result in injustice to the applicant for insurance or to the company. The lines of procedure of the medical examiner are being drawn more sharply and closely, and the time has come when the examiner must be exact, or as exact as possible, and must render decisions based on scientific facts, so far now known.

Dr. Stillman is well known by his work in orthopædic and general surgery, and for exactness and completeness in all the work he undertakes. The book before us is divided into three parts, the first dealing with "Life Insurance Formalities," the medical examiner's report, instructions to medical examiners, the agent's report, and instructions to agents. Part II treats of "Examination of the Applicant," identification, environment, physique, physical diagnosis. Part III relates to the "Diseases relating to Life Insurance," hereditary influences, nutrition and diathesis, etc. An appendix contains legal questions relative to medical examiners, and other matter, including life insurance statistics.

The book contains a superimposed dissected colored plate of the anterior aspect of the body, made by the author, an engraving from life of a candidate stripped for an insurance examination, and a number of engravings of the microscopic appearance of urinary deposits. Life insurance methods are now far beyond those of a dozen years ago, and the books on the subject, written at that time are now out of date. The present work is for the active examiners for life insurance, and to them we can heartily recommend it.

THE MODERN TREATMENT OF DISEASES OF THE LIVER. By PROFESSOR DUJARDIN-BEAUMETZ.

Translated by E. P. HURD, M.D. Published by Geo. S. Davis, Detroit, Mich. Pp. 185. Price 25 cents.

The volume before us is one of the Physician's Leisure Library Series for 1888. The translation is very well made. The book is most interestingly written. As is always true of what Dujardin-Beaumetz writes, much that is now in physiology, as well as what is now in the therapeutics of the diseases discovered, can be found here. The various chapters bear the following titles: The Liver from a Therapeutic Standpoint, Cholagogues, Treatment of Biliary Lithiasis, Treatment of Jaundice, Treatment of Engorgements of the Liver; Treatment of Inflammations of the Liver, Treatment of Hydatid Cysts of the Liver.

MISCELLANEOUS.

A TRAINING SCHOOL FOR NURSES has been opened in connection with the General Public Hospital at St. John, N. B.

DR. H. S. PIGGINS, who for a number of years has been practicing his profession at Caledonia, Minn., has removed to Duluth.

DR. FRANCIS J. GOULD, who died of yellow fever in Jacksonville, Fla., was a native of Lexington, Mass., and a graduate of Harvard, class of 1850. He was 60 years of age.

DR. JOSEPH O'DWYER, the originator of intubation of the larynx, has been appointed Professor of Diseases of Children in the New York Post-Graduate Medical School and Hospital.

MILK SICKNESS.—Isaiah Everly, of Patricksburg, Ind., died of milk sickness on November 1, his widow is seriously ill, and cattle have perished from the disease, which prevailed twenty-five years ago on the same farm.

NO EPIDEMIC AT DEMARARA.—A report from the U. S. Consul at Demarara to the Department of State says that there have been but two cases of yellow fever there, and that his bills of health while showing that the disease exists does not make it appear that it is epidemic.

CHARLES H. PHILLIPS, for many years a prominent manufacturer of chemicals, of New York city, died suddenly of apoplexy, on Nov. 5. He was a member of the

American Geographical Society, President of the C. H. Phillips Chemical Co., and connected with all the prominent societies in his line of business.

A TERRIBLE CATTLE DISEASE is raging in the Philippine Islands. In one province alone over 66,000 animals have died.

THE DISTRICT MEDICAL SOCIETY OF CENTRAL ILLINOIS will hold its semi-annual meeting in the Court House at Vandalia, on Tuesday, November 20, 1888. J. Huber, M.D., of Pana, is President, and J. H. Miller, M.D., of Oconee, is Secretary.

THE SECTION ON DISEASES OF CHILDREN of the American Medical Association, at the last annual meeting, appointed the following committee to investigate the subject of infant feeding, viz.: C. W. Earle, M.D., of Chicago; W. B. Atkinson, M.D., of Philadelphia; and W. S. Christopher, M.D., of Cincinnati, Ohio.

SIX CHILDREN AT A SINGLE BIRTH.—At Dallas, Tex., on Nov. 3, Mrs. Geo. Hirsh, of Navarro county, gave birth to six children. The mother and children are doing well. There are four boys and two girls. All are perfect and fully proportioned, but very small. The babies are all tagged, to preserve their identity.

DAMAGES FOR MALPRACTICE.—That the character of the medical school or sect to which a practitioner of medicine belongs does not relieve him from liability, is shown by a recent decision of the Supreme Court of Wisconsin. C. F. Harrington is a clairvoyant and physician of Madison. He treated a man named Thomas Nelson for many months for rheumatism, whereas he had hip disease, and by reason of this malpractice Nelson was crippled for life. He brought suit against Harrington for damages, and obtained a judgment of \$1,500 in the lower court. Harrington appealed, his contention being that he should be free from liability because Nelson was fully aware of the peculiar medical school to which he belonged. The Supreme Court confirmed the judgment of the lower court, holding that the question of the character of the medical school in no manner whatever relieved a doctor from liability for malpractice. This is the first time on record, we believe, that this peculiar phase of this question has come up in the high courts.

HEALTH IN MICHIGAN.—For the month of October, 1888, the reports indicate that tonsillitis, neuralgia, typhomalarial fever, influenza, bronchitis and scarlet fever increased, and that diarrhœa, dysentery, cholera morbus, decreased in prevalence.

Compared with the average for the month of October for the nine years, 1879-1887, the reports indicate that consumption of the lungs, intermittent fever, diarrhœa, remittent fever and tonsillitis were less prevalent in 1888. For the month of October, 1888, compared with the average for corresponding months in the nine years, 1879-87, the temperature was lower, the absolute humidity and the day and night ozone were less, and the relative humidity was about the same.

Including reports by regular observers and others, diphtheria was reported present at thirty-six places in Michigan in October, 1888, scarlet fever at thirty-two places, typhoid fever at forty-three places, and measles at seven places.

Reports from all sources show diphtheria at sixteen places more, scarlet fever at eight places more, typhoid fever at eight places more, and measles at the same number of places in October, when compared with the preceding month.

THE SOUTHERN SURGICAL AND GYNECOLOGICAL ASSOCIATION will hold its first annual meeting at Birmingham, Ala., December 4, 5 and 6, 1888. The officers for 1888 are: President, Dr. W. D. Haggard, Nashville, Tenn.; Secre-

tary, Dr. W. E. B. Davis, Birmingham, Ala.; Judicial Council, Dr. John S. Cain, Nashville, Tenn., Dr. Hunter McGuire, Richmond, Va., Dr. J. M. Taylor, Corinth, Miss., Dr. DeSaussure Ford, Augusta, Ga., Dr. R. A. Kinloch, Charleston, S. C.; Chairman Committee of Arrangements, Dr. J. D. S. Davis, Birmingham, Ala.

FIRST DAY.—MORNING SESSION.

The Association will be called to order by the President at 10 o'clock, A.M.

Prayer by the Rev. D. I. Purser, D.D.

Address of Welcome, by Hon. A. O. Lane.

Reading of Minutes.

Report of the Committee of Arrangements.

Report of the Judicial Council.

Miscellaneous Business.

The Annual Address of the President, Dr. W. D. Haggard, Nashville, Tenn.

Papers.—Gastrostomy, by W. B. Rogers, M.D., Memphis, Tenn. Superinvolution of the Uterus following Trachelorrhaphy, by Virgil O. Hardon, M.D., Atlanta, Ga. Indications for Operative Interference in Cerebral Troubles, T. O. Summers, M.D., Jacksonville, Fla. A Case of Tubal Pregnancy, presenting Interesting Medico-Legal Relations, E. P. Sale, M.D., Memphis, Tenn. The Extravagancies and Impractical Requirements of Modern Antiseptic Surgery, so far as the Country Practitioner is Concerned, by J. M. Taylor, M.D., Corinth, Miss. Antiseptics in Surgery and Gynecology, by F. T. Meriwether, M.D., Asheville, N. C. My Antiseptic Bags; or Practical Aseptic Surgery, by J. W. Long, M.D., Randleman, N. C.

Adjournment at 2 P.M.

Excursion to North Birmingham at 3:45 P.M.

EVENING SESSION, AT 8 P.M.

The Annual Oration, by Dr. W. F. Hyer, of Meridian, Miss., at O'Brien's Opera House. After the Oration the audience will be entertained by the Mendelssohn Club.

SECOND DAY.—MORNING SESSION, AT 9:30 A.M.

Report of Treasurer.

Report of Judicial Council.

Miscellaneous Business.

Papers.—Floating Kidney, with Vicarious Menstruation, by DeSaussure Ford, M.D., Augusta, Ga. New Treatment of Intra-Uterine Fibroids, by E. J. Beall, M.D., Fort Worth, Texas. The Medical Treatment of Fibroid Tumors of the Uterus, by Bedford Brown, M.D., Alexandria, Va. Alexander's Operation, by W. L. Nichol, M.D., Nashville, Tenn. The Present Status of Electro-Therapeutics in Gynecology, by J. R. Buist, M.D., Nashville, Tenn.

Excursion to Gate City at 3:45 P.M.

EVENING SESSION, AT 8 P.M.

Hysterectomy in Cancer of the Uterus, by W. H. Wathen, M.D., Louisville, Ky. Fractures of the Forearm, by Jno. Brownrigg, M.D., Columbus, Miss. Treatment of Fractures with Plaster of Paris Splints, by W. F. Westmoreland, Jr., Atlanta, Ga. Interesting Cases of Surgery, by R. M. Cunningham, Pratt Mines, Ala. The New Departure in Uterine Therapeutics—the Dry Method, by T. A. Means, M.D., Montgomery, Ala. A Study of the Various Methods of Treatment of Laceration of the Perineum and Rectocele, with Report of Cases, by J. H. Blanks, M.D., Meridian, Miss. Perineal Lacerations, by M. C. Baldrige, M.D., Huntsville, Ala.

THIRD DAY.—MORNING SESSION, AT 9:30 A.M.

Report of Judicial Council.

Unfinished and Miscellaneous Business.

Papers.—Cystoscopic Explorations, by A. V. L. Brokaw, M.D., St. Louis, Mo. Shock of Injury and Its Effects, by Jno. R. Page, M.D., Birmingham, Ala. Some Practical Thoughts in Surgery and Gynecology, by James Guild,

M.D., Tuscaloosa, Ala. The Field and Limitation of Laparotomy, by I. S. Stone, M.D., Lincoln, Va. Operative Procedures in Epilepsy, by J. T. Wilson, M.D., Sherman, Texas. Surgical Tuberculosis, by W. Locke Chew, M.D., Birmingham, Ala.

AFTERNOON SESSION, AT 3 P. M.]

Treatment of Certain Forms of Menorrhagia, with Report of Cases, by W. D. Bizzell, M.D., Atlanta, Ga. Electrolysis in the Treatment of Urethral Strictures, by S. M. Hogan, M.D., Union Springs, Ala. Operative Procedures in Hypertrophy of the Prostate, by R. D. Webb, M.D., Birmingham, Ala. Electrolysis in Morbid Alterations produced in the Prostate by Gonorrhœa of the Urethra, by J. D. S. Davis, M.D., Birmingham, Ala. Dermoid Cysts of the Coccygeal Region, by E. J. Beall, M.D., Fort Worth, Texas.

EVENING SESSION, AT 8 P. M.

Discussion—Abdominal Surgery.
Election and Installation of Officers.

Official List of Changes in the Stations and Duties of Officers Serving in the Medical Department U. S. Army, from November 3, 1888, to November 9, 1888.

Lieut.-Col. Basil Norris, Surgeon, will be relieved from duty in the Department of the Columbia by the commanding General of that Department, and will report in person, on or before November 14, 1888, to the commanding General Div. of the Pacific, for duty as Medical Director of that Division and of the Department of California. Par. 14, S. O. 255, A. G. O., Washington, November 1, 1888.

By direction of the Secretary of War, Lieut.-Col. Edward P. Vollum, Surgeon, on being relieved from duty as Medical Director Dept. of Texas by Lieut.-Col. Joseph C. Baily, Asst. Medical Purveyor, under War Department order dated October 31, 1888, S. O. 255, A. G. O., will repair to New York City, assume the duties of acting Asst. Medical Purveyor, and take charge of the medical purveying depot at that place. Par. 2, S. O. 255, A. G. O., Washington, November 1, 1888.

Lieut.-Col. Charles T. Alexander, Surgeon, is relieved from further duty in the Dept. of Dakota, and will report in person to the commanding General Dept. of the Columbia for duty as Medical Director of that Department. Par. 14, S. O. 255, A. G. O., Washington, November 1, 1888.

Col. Joseph C. Baily, Asst. Medical Purveyor, is, at his own request, relieved from the charge of the medical purveying depot in New York City, and is, by direction of the President under the provisions of the Act of Congress approved June 23, 1874, assigned to duty as surgeon in the Medical Department. He will report in person to the commanding General Dept. of Texas for assignment to duty as Medical Director of that Department, to relieve Lieut.-Col. E. P. Vollum, Surgeon. Par. 1, S. O. 255, A. G. O., Washington, November 1, 1888.

By direction of the Secretary of War, Lieut.-Col. Joseph C. Baily, Asst. Medical Purveyor, will transfer at once the public funds for which he is now responsible to Capt. Henry Johnson, Medical Storekeeper, who will assume temporary charge of the medical purveying depot in New York City, retaining charge thereof until relieved in person by Lieut.-Col. E. P. Vollum, Surgeon, under his assignment as acting Asst. Medical Purveyor, to whom Capt. Johnson will then transfer the public funds. Par. 1, S. O. 257, A. G. O., Washington, D. C., November 3, 1888.

Major Henry McElderry, Surgeon U. S. Army, granted leave of absence for two months, by direction of the Secretary of War, to take effect on the completion of his present duties. Par. 3, S. O. 256, A. G. O., Washington, D. C., November 2, 1888.

Capt. Clarence Ewen, Asst. Surgeon, is relieved from duty at Ft. Sidney, Neb., to take effect on the expiration of his present leave of absence, and will report in person to the commanding officer, Madison Bks., N. Y., for duty at that post. Par. 2, S. O. 258, A. G. O., Washington, November 5, 1888.

Capt. Daniel M. Appel, Asst. Surgeon, is relieved from duty at Ft. Davis, Texas, and will report in person to the commanding officer, Ft. Sill, Ind. Ter., for duty at that post, reporting by letter to the commanding General Dept. of the Missouri. Par. 2, S. O. 258, A. G. O., Washington, November 5, 1888.

Capt. J. Van R. Hoff, Asst. Surgeon, is granted leave of absence for one month, with permission to apply for an extension of one month. S. O. 134, Dept. of the Missouri, Ft. Leavenworth, Kan., November 1, 1888.

Capt. Curtis E. Price, Asst. Surgeon, granted leave of absence for two months, with permission to apply for an extension of ten days. Par. 2, S. O. 257, A. G. O., Washington, November 3, 1888.

Capt. Marshall W. Wood, Asst. Surgeon, granted leave of absence for one month, with permission to apply for an extension of ten days. Par. 2, S. O. 257, A. G. O., Washington, November 3, 1888.

By direction of the Secretary of War, Capt. John J. Cochran, Asst. Surgeon, is relieved from temporary duty at Hdqrs. Div. of the Pacific, and will report in person to the commanding officer, Ft. Adams, R. I., for duty at that post. Par. 2, S. O. 256, A. G. O., Washington, November 2, 1888.

By direction of the Secretary of War, Capt. Norton Strong, Asst. Surgeon, is relieved from duty in the Dept. of Ariz., and will report in person to the commanding officer, Ft. Schuyler, N. Y., for duty at that post, and by letter to the commanding General Div. of the Atlantic. Par. 4, S. O. 255, A. G. O., Washington, November 1, 1888.

Capt. W. O. Owen, Jr., Asst. Surgeon, Ft. Leavenworth, Kan., will proceed at once to Ft. Sill, Ind. Ter., and report to the commanding officer for temporary duty at that post. Hdqrs. Dept. of the Missouri, S. O. 133, par. 1, Ft. Leavenworth, Kan., October 30, 1888.

By direction of the Secretary of War, First Lieut. James D. Glennan, Asst. Surgeon, recently appointed, will repair from this city to Willets Point, N. Y., and report in person to the commanding officer of that post for duty. Par. 3, S. O. 255, A. G. O., Washington, November 1, 1888.

By direction of the Secretary of War, First Lieut. Alfred E. Bradley, Asst. Surgeon (recently appointed), will report in person to the commanding officer, David's Island, N. Y., for duty at that depot, reporting by letter to the Superintendent of the recruiting service, New York City. Par. 14, S. O. 260, A. G. O., November 7, 1888.

Official List of Changes in the Medical Corps of the U. S. Navy for the Week Ending November 10, 1888.

Surgeon D. Dickinson, ordered to Naval Hospital, Mare Island, Cal.

Surgeon G. P. Bradley, detached from Naval Hospital, New York, and to "Iroquois."

Surgeon R. C. Persons, detached from Army and Navy Hospital, Hot Springs, Ark., and to Naval Hospital, New York.

P. A. Surgeon Ernest Norfleet, detached from Naval Hospital, Mare Island, Cal., and to the "Trenton."

Asst. Surgeon H. N. T. Harris, detached from Naval Hospital, Mare Island, Cal., and to the "Kearsarge."

Asst. Surgeon J. S. Sayre, ordered to examination for promotion.

P. A. Surgeon H. G. Beyer, detached from "Trenton" and granted six months' leave, with permission to leave the United States.

Patrick H. Bryant and Luther L. von Wedekind, commissioned Asst. Surgeons U. S. Navy.

THE TREATMENT OF PERITONITIS.

Read in the Section on Gynecology at the Thirty-ninth Annual Meeting of the American Medical Association, Cincinnati, May, 1888.

BY WM. H. MYERS, M.D.,
OF FORT WAYNE, IND.

PATHOLOGICAL DEFINITION OF PERITONITIS.

"Increased vascularity-softening or thickening of the peritoneal membrane, with effusion of coagulable lymph, or of a sero-albuminous or sero-puriform, or sero-sanguineous fluid, sometimes with organized adhesions." Copland.

When Dr. Rushton Parker asserts in his article on Peritonitis, published in the "Dictionary of Practical Surgery," that "the treatment of peritonitis is simple enough whatever be its cause," and that "opium, alcohol and liquid diet is the treatment that may be uniformly adopted in all its forms," he fails to apprehend that it is only through a perfect diagnosis in each case that we can see in what direction surgical or therapeutical interference should be attempted; for connected with the treatment of peritonitis are several questions I will submit for your consideration:

Is acute peritonitis ever idiopathic?

Is it a symptom or a disease?

Is it always septic?

Again I may ask—

Does the treatment properly belong to the physician or surgeon?

In your answer you will be brought irresistibly back to diagnosis, since from it all treatment must flow. It is then of primary importance that in every case the ætiology be definitely settled at the earliest moment. When we have arrived at the conclusion that peritonitis is present or impending, and we have discovered the cause, the blow must be struck simultaneously with the advent of the enemy; no delay can safely be tolerated, the only hope of rescue being the sudden arrest of the disease. We must learn the beginnings. As remarked by Sir William Gull: "Often when the gathered clouds of the final storm have filled the atmosphere it is in vain that we look around to see from what point of the Heavens it began." By the time that the normal outlines of the abdomen are obscured by tympanitic distension, respiration quickened and shallow, the pulse rapid and wiry, the supreme moment for precise diagnosis is past.

What are the grounds for a true discrimination? Certainly not the teaching that acute peritonitis may be idiopathic in a healthy subject. Upon this subject Dr. Savage, of Birmingham, England, in 1885, expressed the following opinion: "We are learning, if we have not already learned, to look upon peritonitis as a symptom of some organic change and not as a disease in itself; and this is well for our patients, because operative measures can do much for it; we shall ere long regard so-called 'idiopathic peritonitis' almost as a curiosity." Professor Bartholow's opinion is, that the great majority of cases of peritonitis come from previous disease in the peritoneal or pelvic cavity. He believes it to be extremely rare, indeed, for an idiopathic case to occur. Habershorn refers to 3,752 inspections made in Guy's Hospital; 501 were instances of peritonitis, but could not find a single case that he considered idiopathic. "A pure idiopathic peritonitis is difficult to realize under any circumstances; in puerpera it is impossible." Barnes.

Believing as I do, that acute peritonitis is never idiopathic but must be septic I am compelled to believe that the treatment must be modified in accordance with these views.

THE EVOLUTION OF THE TREATMENT OF PERITONITIS AFTER LAPAROTOMY.

On January 1, 1859, Sir Spencer Wells made an abdominal section and removed an ovarian tumor; the patient died thirty-two hours after. One hour after the operation she had a pulse of 100, and complained of some pain; a suppository containing $\frac{1}{3}$ grain of morphine was passed into the rectum; two other suppositories at intervals of half an hour; a sixth suppository at midnight; pulse 130; 9 A.M., pulse 124; eighth suppository at noon. The autopsy revealed the presence of peritonitis. A considerable amount of free liquid was present in the cavity generally; the fluid had a pungent, irritating effect upon the skin. Sir Spencer in reviewing the case asks the pertinent questions:

What was the cause of death?

Did she get too much opium? Two grains of

morphine within ten hours and 1 grain in the succeeding twelve hours. He dismisses this consideration and asks "Did she die of peritonitis?" This question he answers thus: "My impression is, that if peritonitis killed her, it was indirectly by the formation of a morbid poison; the serum was very acrid." "If then my patient could generate a poison capable of killing other people may it not have killed her?" His practical commentary is in these words: "It may possibly be advisable, in some cases, to provide for a free outlet of the effused serum." (It was about this period when Baker Brown quailed before what he called peritonitis as a cause of death after ovariectomy.) These reflections were followed by the introduction of the drainage-tube and drainage of the peritoneal cavity.

Sir James Paget said in 1862, in an address delivered before the British Medical Association, that "some of the deaths after surgical operation were preventable; and that "the mortality will be reduced if the members of the Association will decide that it shall be."

In 1864, Sir Spencer Wells directed attention to the existence of germs in the atmosphere, and advised precautions against their entrance from without or their development within, in abdominal sections. In 1877 Lister arrived in London, and the questions of aseptic and antiseptic surgery, and their applicability to ovariectomy were considered; for in the inflammatory products within the peritoneal cavity, the effusion, germs were found; living organisms with an indefinite power of reproduction, and when once implanted in a suitable soil multiplying indefinitely. This is the doctrine of the day.

Germs are living. All living things require certain conditions for their growth and development; vitality their poison, non-vitality their food. We do not propose to enter into the question, whether microorganisms be the cause or result of the morbid processes with which they are associated, but to study the methods of interference: 1. By removing the germs; 2. By removing the soil in which they grow.

Microorganisms outside the body, can be destroyed by germicides; but when they have once gained entrance and are inside the pelvic cavity all we can do is to sustain the organism, in the struggle for existence between the cells which compose it and the bacteria which have invaded it. The clinical means most highly valued are opium by the physician; salines drainage and surgical procedures, when necessary, by the surgeon.

Grailly Hewitt, of London, in 1868, quotes Mr. Clay as saying:

"The chief mortality, 48 per cent., arises from peritonitis after ovariectomy." Baker Brown after a series of disasters utters the truism: "It's the peritonitis that beats us." Tait now informs us

that now we beat the peritonitis; on the slightest indication of its appearance, after ovariectomy, we give a rapidly acting purgative, it matters not what, the patient's bowels are moved, and the peritonitis disappears." "This practice," says Tait, "was introduced by me in 1875, and is now almost uniformly adopted." He continues: "How different from the views we had drilled into us years ago, that opium was the sheet anchor of the practitioner in all abdominal troubles, when I say that all opiates are forbidden in my practice."

This may be regarded as the latest phase in the evolution of the treatment of peritonitis after abdominal sections. This I regard as the greatest advance that has been made, and to Mr. Tait is solely due the credit of it. In reply to a letter of recent date he writes as follows:

7, The Crescent, Birmingham, April 16, 1888.

Dear Sir:—Thanks for your very kind letter. I am perfectly satisfied, and I think the majority of practitioners who have tried it also agree that the best treatment for peritonitis, especially when occurring after an operation, is an early administration of saline cathartics. It is a practice which I had not seen the slightest reason to depart from.

Yours very truly,

LAWSON TAIT.

In a letter from Dr. Joseph Price, of Philadelphia, occurs the following statement with reference to the treatment of acute peritonitis: "I hold very strong convictions in the strictly good effects produced by the free use of salines; they do most decidedly imperil the safety of the many germs, beside relieving the overloaded and inflamed tissues and congested conditions of all the abdominal and pelvic viscera. I have not the power of too strongly urging the use of salines upon the slightest indications of local or general peritonitis. I have never known them to disturb in any way the vital power other than to benefit."

Dr. Charles B. Penrose, of Philadelphia, sent the following reply to a letter requesting his experience in the treatment of acute peritonitis.

"My experience is limited altogether to peritonitis following laparotomy; in all cases of abdominal section, sulphate of magnesia or Rochelle salts is administered in a large dose the moment any tendency to undue distension or general abdominal pain is noticed. I think that when patients survive the first shock of peritonitis, they die subsequently from the same causes which produce death in intestinal obstruction from other causes. At the onset of the peritonitis it may be absorbed by salines; after it is well under way, however, I think that the salines save life by overcoming the intestinal obstruction. I think that statistics show beyond a doubt the superiority of the saline treatment over the opium treatment, at least after laparotomy." Speaking of the one hundred consecutive successful cases of laparotomy by Dr. Price and himself, he says he can-

not recall one case in which opium, even paragon, was given.

Grieg Smith in his work upon "Abdominal Surgery," in the first edition, says: "After abdominal operations if peritonitis, local or general follow, opium is not the best treatment. As a rule, sedatives are to be condemned. I had oftener than once recourse to a saline purge in peritonitis; a purge carries off great quantities of gas and fluid, relieves the distension, and probably by its physiological action relieves engorgement of intestinal vessels."

Grieg Smith in the second edition of his work says: "Over and over again, I have been able to demonstrate to students and medical men, the value of a saline purge in case of incipient peritonitis. In grave abdominal cases I positively like to see diarrhoea natural or artificial. Slowly, but surely, the therapeutic virtues of purges in operation are being recognized. Among the most enthusiastic supporters of the plan are such well-known surgeons as Gill Wylie, Baldy, Penrose, and Gardner." Here he quotes the last named as saying: "In my work during the year I have given no opium, and invariably, immediately after the appearance of distension, pain, vomiting, I have given purgatives with the most signal advantage.

We are not so completely impressed with the authoritative decisions of tradition as to believe the rational treatment of acute peritonitis to be—to benumb the sensibilities, reduce the respirations, and contract the pupils with opium in heroic doses; rather should we prevent the presence of germs and expel them from the pelvic cavity by drainage.

Narcotics.—For opium, its advocates claim that pain is annulled, the nervous system tranquilized, sleep induced, the shock lessened and the peristaltic movements of the bowels arrested.

Salines.—For these, their advocates claim that by their use, we "imperil the germs," deplete congested peritoneal vessels, and drain off through the intestines serum contained in the peritoneal cavity.

While we admit that opium relieves pain, we also claim that it prevents the escape of poisonous products. We also deny that it is necessary to give opium to arrest peristalsis, for the reason that in an acute attack of peritonitis complete paralysis of the muscular walls of the intestines exists, destroying its function and producing often obstruction.

In support of this view, Godlee (as to the diagnosis in peritonitis) says: "It seems worth emphasizing that peritonitis *per se* ought always to be considered as one of the possible causes of intestinal obstruction, and that the complete absence of visible peristalsis is an important indication of its presence."

Charles Penrose, in an article published in the

Medical and Surgical Reporter, Philadelphia, says: "The danger of moving the bowels after exposure of the peritoneum has been much exaggerated. It seems probable that the peritoneum is subjected to at least as much irritation from the tension and movement caused by the distending gas as it would be from any peristaltic motion of the muscles of the intestines."

We are advised to keep the bowels in splints; this is in direct conflict with the law that micro-organisms require the condition of rest for their development; they will not multiply in the circulating blood. I had one painful experience where I kept the bowels in splints, after an ovariectomy; during the first week nothing untoward happened, but on the seventh day peritonitis supervened, until on the fourteenth day, when she died with symptoms of strangulation and the autopsy revealed that it depended upon adhesive bands, uniting coils of intestines. Had I prescribed a saturated solution of sulphate of magnesia and kept up a peristaltic action, the formation of false bands and adhesions could not have occurred. In confirmation I will refer to the *Berliner Klinische Wochenschrift*, January and February, 1874.

On the 28th of June, 1887, I made an abdominal section and removed both ovaries; they were cystic; on the second day following a chill and rapid development of peritonitis. I immediately gave half an ounce of saturated solution of sodæ et potass. This was followed by profuse watery discharges; the vomiting ceased; the tympanitis disappeared, the pulse and temperature declined in a few days becoming normal—complete recovery.

On the 13th of November, 1887, I was called to visit Mrs. C., æt. 36. I found a ventral hernia with strangulation; the tumor the size of the double fist; symptoms urgent. The taxis having failed laparotomy was decided upon, stricture divided reduction and excision of the sac; the peritoneal cavity closed by stitches, the final dressing as after ovariectomy. On the third day she had a severe chill, pain followed by vomiting, tympanitic, distension of the abdomen. Pulse, 120, temperature 101°. Treatment, heroic doses of opium prescribed by the attending physician. I ordered the opium discontinued and gave a full dose of magnesia; copious purgation followed, after which the peritonitis rapidly subsided and the patient speedily recovered.

Traube reports a case of a patient affected with general peritonitis, and in whom after death no adhesions or bands between the folds of intestines existed, although there were distinct evidences of false membranes on the parietal peritoneum. He attributes this unusual occurrence to the fact that the patient before death, had suffered from diarrhoea; he believes that constant peristaltic movements, which take place owing to intestinal

irritation, prevent the formation of adhesions and break those which may be formed. He accordingly questions the advisability of keeping the intestines at rest; claims that it facilitates the formation of adhesions; he is not convinced that inflammation is increased by the peristaltic movements, and suggests that peritonitis be treated by aperients.

While Treves advocates the use of opium in peritonitis, he admits that the clinical outlines of the case may be consequently blurred and serious errors in the diagnosis result in consequence.

THE DANGERS OF PERITONITIS.

The trinity of peritonitis, tympanitis and vomiting are the Furies of abdominal surgery.

In 1868, Baker Brown reported 111 cases of ovariectomy and thirty-five deaths. Speaking of the danger to be apprehended, places prominently, acute peritonitis as of most frequent occurrence; he gave opium in heroic doses, and finally says: "My experience has not given me that confidence in opium which most physicians possess." Peaslee, in 1872, in discussing peritonitis after ovariectomy said: "Give opium in quantities sufficient to remove the pain, and especially by hypodermic injection of muriate of morphine $\frac{1}{4}$ to $\frac{1}{2}$ grains, every two hours or oftener.

In 1872, Sir J. Y. Simpson in a lecture on ovariectomy, said: "Perhaps the most frequent cause of death in connection with the operation is peritonitis. The treatment is opium."

Barnes in 1874, in his treatise upon this subject, recommends leeches, opium and mercury.

Thomas said: "Peritonitis, which proves the cause of death in about one-fourth of all who die from this operation, (ovariectomy) should be treated by full doses of opium.

In the International Encyclopedia of Surgery, 1886, we find the following: "After ovariectomy peritonitis is to be counteracted by increased doses of morphine hypodermically or by the rectum (Chas. Caurel Lee, New York).

In 1866, Dr. Gardner, of Canada, opened the peritoneal cavity thirty-eight times with three deaths, and he declares that, "experience has taught him that opium in most cases is more harmful than beneficial."

TREATMENT OF ACUTE PERITONITIS BY ABDOMINAL SECTION.

I believe that we ought to advocate and practice free incision drainages as practiced in the joints and in the inflammatory conditions of the pleura. The question of operative treatment in puerperal, as well as in other forms of peritonitis, has been strongly presented in a paper by Dr. Chalmers on Puerperal Septicæmia before the British Gynecological Society.

Lawson Tait in a recent publication declares, "I have now come deliberately to the conclusion that it is an act of almost criminal omission to

allow a case of peritonitis to die without abdominal section." Dr. Barnes has expressed similar views. Whenever pus has formed and collected in the abdomen and pelvis, he believed the indication was strong to make an incision so as to give it exit. This is in accordance with the rules of surgery in the brain, in the pleural cavity, and why not in the abdomen.

In a letter from Grieg Smith upon the surgical procedure, he writes as follows:

16 VICTORIA SQUARE, CLIFTON, April 6, 1888.

My Dear Sir:—In treating suppurative peritonitis by operations I am gradually coming to the belief that treatment with a wet and not a dry peritoneal cavity is advisable. The intestines are kept floating in a warm and mildly antiseptic fluid for one or two days, or even longer. I think it prevents the formation of adhesions, and consequent gaseous distension with its serious consequences.

J. GRIEG SMITH.

From the above quotations we are led to infer that opium is the routine remedy in acute peritonitis; is believed in as profoundly as if it were a religious dogma, and Professor Clark is referred to in the same spirit that actuated the Church of Rome in her appeal to the Greek Fathers to sustain her supremacy.

That the acceptance of an opinion in medicine does not afford evidence of its truth, is well illustrated by the fact that the sanguinary doctrines held by Professor Charles D. Meigs are now only found in his books, and not adopted as formerly by clinicians. It will be well to remember that the influence of authority in matters of opinion, does not prove that numerous persons have carefully examined the questions upon its own merits, and have founded their conclusions upon an independent investigation of the evidence. So the number of authorities adduced has, in fact, no weight, and thus their numbers alone are no more entitled to be considered as independent observers than the successive compilers who transcribe an historical error are entitled to be reckoned as independent witnesses.

DENTOGENY.

Read in the Section on Dental and Oral Surgery, at the Thirty-ninth Annual Meeting of the American Medical Association, May, 1888.

BY WILLIAM C. BRITTAN, M.D.,

OF DETROIT, MICH.

The first indication of tooth development in the human embryo is noticeable at a period somewhere about the fortieth day of fetal life, and consists simply of an increased thickening of the epithelium over that part which is to form the future alveolar border.

At this time may be found, sometimes, not always, upon the lingual surface a slight depression or groove, the "dentinal groove" of writers, which when present consists of an infolding only of the mucous tissue, and is usually more marked

anteriorly than elsewhere. As, however, it is not always present, no histological importance can reasonably be attached to it. Later a change is seen to occur at certain points in the cells of the epithelium, consisting of an enlargement of the cells and their nuclei, these points corresponding nearly to the position of the future teeth. This changed epithelial structure dips down into the adjacent embryonic tissue in the form of "cords," or rather of tubular glands (Plate 1). The cells of the outer layer of these cords have a columnar form, yet they are seen to have now lost much of their resemblance to those of the columnar layer of the epithelium with which they are said to be identical. Plate 2 shows one of these cords highly magnified.

These epithelial cords constitute the embryonic enamel elements and later form what is known as the "enamel organ," which is concerned mainly—but not wholly—in the production of the enamel of the tooth. Coincidentally with the above changes an increased activity has been in progress in the submucous tissue adjacent to these cords resulting in a multiplication of its cells and a consequent increased density of this tissue at points which occur sometimes beneath the cords, sometimes at one side (Plate 1-D.) and often one upon each side, in which case the enamel elements for two separate teeth of the same type are furnished from one cord.

These cell clusters of the submucous tissue gradually assume a papilliform appearance, pushing up against the overlying cord, in which they soon become nearly enveloped, and now constitute the so-called "dentine germ, or organ." In these two germs—the enamel and the dentine—we have the prime factors of tooth-building. And the processes here employed furnish problems many of which are yet unsolved. The interpretations which we shall give are solely the result of our own study of these tissues. The micrographic illustrations are from some of the preparations used for that purpose, and the preparations themselves are from the human embryo. If we err in any of the statements here made it is quite consoling to know that all other writers upon this subject have done the same. We believe, however, that we are well fortified.

Rapid developmental changes now occur. The cord, by a separation of its walls, assumes a somewhat "stirrup-like" form, its base conforming to the contour of the "dentine organ" until by the upward growth of the same all that part which is to compose the crown of the tooth is covered by the enamel organ in the form of a cap (Plate 3) which now separates itself from the original cord by the breaking up of that structure.

In this connection we would suggest that the prevailing dogma that the enamel organ for the second set of teeth is supplied from the cords of the first is incorrect. As a matter of fact they are

derived directly from the mucous epithelial layer just as in the first instance.

All the above changes occur previous to deposit of either enamel or dentine, but we now have both these organs in a stage of development nearly sufficient to begin that work, and from this point the progress of development is much slower than previously.

We will now, by referring to Plate 3, note some of the changes that have taken place in the "enamel organ" in its transition from the cord with its outer wall of columnar cells to its present condition. By the separation of its walls in the course of its development the cells of its interior have by growth and separation, and attachment to one another by their processes, now assumed the form of stellate cells, and now constitute that part of the organ known as the "stellate reticulum (B), the exact function of which is not understood. This structure occupies all that part lying between the inner and outer investments, viz.: the wall in contact with the dentine organ (D) and that in contact with the sacculus proper (E) which latter is the product of the contiguous embryonic tissue. Further, that at the point where the enamel organ embraces the *apical portion of the embryonic tooth (G) the wall of the organ is folded upon itself*, thus bringing both walls (D and E) into mutual contact. These walls, although originally one and the same, here diverge, and now form two distinct and well differentiated structures. We also note that the outer investment (E) has lost all appearance of a columnar cell layer which characterized the original cord, and is now composed of a system of vessels and capillaries distributed through a fibrous membrane whose cells (mostly fusiform) now lie parallel to its surface.

At the inner wall (D) a very great change has also taken place. Here the original columnar form of the cells is still preserved at this stage of development, although greatly reduced in size, and having also lost other marked features of structure. Plate 4 gives a very good illustration of this boundary highly magnified.

The changes above mentioned as occurring in these two investments might with some show of reason be accounted for as due somewhat to mechanical influences. For instance, the outer wall (E—Plate 3) in assuming its convex form in which we now find it would, so to speak, be put upon the stretch. In consequence its cells would be forced into a horizontal position. On the other hand there would be a crowding together of the cells in assuming a concave form in the inner wall (D) thus maintaining their columnar form. These walls (D and E) or boundaries are said to be identical with the so-called "malpighian" layer of the epithelium, the columnar cells of which (D) are here transformed into "ameloblasts," or enamel forming cells.

No. 4. X 300.

No. 5. X 1000.

No. 6. X 75.

To ascertain, if possible, how far this is a fact, let us examine a little into some of the structural characteristics of the tissues here involved. The saculus, as before intimated, is the product of the surrounding embryonic tissue, and exhibits two well differentiated structures, the outer layer being composed of fibrous connective tissue elements of a somewhat loose texture, while the inner, or that in contact with the outer investment of the reticulum, is in structure much finer and contains a profusion of nucleated bipolar cells with long and highly refractive processes, and lying mainly parallel to the surface of the organ in the outer wall of which they seem to be interwoven and to connect upon the other side directly with the processes of the stellate cells of the reticulum. Again the processes of the cells form a like connection with those of the "stratum intermedium," and these last are seen to form true axial connections with the columnar cells of the ameloblastic

deated enlargements occur in them. Thus they become those columnar bodies known as "odontoblasts," to which we shall refer again further on.

We know that in these, as in the case of all the other tissues of the body, whatever elements are required for the work of building are derived from blood constituents. We know, also, that the enamel organ is *extra vascular*, the nearest approach of blood capillaries being at its outer investment (Plate 3, E) on the one side, and the dentine organ on the other. Therefore it is clear that such supply must come from the point first mentioned. The blood constituents passing through the reticulum, probably there receive such elaboration as fit them for their final place of deposit. Herein, then, consists the function of this stellate structure.

An examination of the section represented in Plate 3 shows that a change is in progress at the nuclei of the stellate cells in the immediate vicin-

layer, or, as we prefer to call it, the enamel matrix. (Plate 3, D). At the point of juncture of the cells of the stratum intermedium with those of the matrix they are joined by lateral processes. Sometimes two or more of these joinings are seen, thus forming those transverse lines which mark the upper boundary of the matrix cells, which are again joined at their lower ends where they come into contact with the dentine organ in just the same manner; and thus is formed the transverse line which marks the boundary here. And thus also is formed the supposed membrane lying between the enamel and the dentine, and which consists simply of a mesh or network composed of the lateral processes of the matrix-cells. These matrix-cells also send axial processes beyond this border line and into the dentine organ, where nu-

ity where a deposit of enamel is about to occur—noticeable as a *marked increase in size*. They now appear as highly refractive spherical bodies of an opalescent character. Coincidentally with or a little before the first deposit of enamel, two or more courses of these bodies make their appearance in the upper part of the matrix cells (Plate 5, D), where they have been termed the nourishing cells of the enamel organ. These spherical cells, or nuclei, are not, however, developed within the enamel matrix, but are identical with those of the reticulum (C), and probably constitute the calcific elements of the enamel. They, by some means, find way within the matrix cells where, superimposed one upon another, by some unknown law, coalescence occurs, thus forming the rods or prisms of the enamel, the matrix cell walls becoming the

cement substance between the same. In this we have a perfect explanation of the striated appearance of the enamel rods—an appearance that cannot be reasonably accounted for in any other way. It is a well known fact that by treating the enamel with alkalis, the rods may be divided into minute cubical sections just in the places where these striations occur. We submit, therefore, that each of these little sections represents an original spherical body or *nucleus* which was developed within a stellate cell of the reticulum.

Associated with the first deposit of the enamel, which occurs very nearly coincidently with that of the dentine, another very marked change takes place, consisting of an increased density in that part of the reticulum lying in contact with the matrix cells (Plate 5, B). This occurs in consequence of the upward push of the growing tooth-germ, accompanied with the increasing enamel deposit, which now so encroaches upon the reticulum that it here becomes folded or gathered back upon itself, thus forming that line known as the stratum intermedium (Plate 5, E). In Plate 4 it will be noticed that this structure is not yet developed. In consequence of this folding back of this structure it may be presumed that the nuclei lying in the deeper parts of the organ are brought into more intimate association with the matrix cells, thus favoring their migration. Plate 5 gives quite a good illustration of this. Here a portion of the matrix (D), stratum intermedium (B), and the reticulum (C), have been torn out from the enamel organ and left attached to the already formed dentine (A). As a result also of the outward push of the growing tooth, the matrix associates with what remains of the reticulum, and its outer investment becomes an attenuated layer over the apex of the tooth, and gradually assumes that form over the whole crown as the process of deposit is completed. In this we have the *mythical* "membrane of Nasmyth."

At this stage the enamelization of the tooth is nearly completed; but the function of the organ, or rather what now remains of it, does not end here, as we shall see. In Plate 6 we have represented an embryonic deciduous canine tooth with its investments at about the above stage of development. In making this section the enamel organ and the layer of last formed enamel was torn from its position, making quite a space (C) upon the labial side. Upon the palatine side the enamel organ (B) is intact, but with a disarrangement of the last formed enamel (E); yet quite a thick layer still covers the dentine, distinguishable from the latter by its higher color (F). At the base of the rudiment is seen a dark knotted line (H) composed of vessels and capillaries to cross section. Here is the growing point of the tooth. It is at this point that the crown begins and at this point that the root is finished. Immediately below this point is the base of the sac-

culus, and in contact with that the forming jaw bone (I). We note that the line (H) is joined by the lower borders of the enamel organ (B), thus completing the circuit. At this point of juncture (K) the two walls of the organ are in mutual contact. A little higher up, at (J), is the cervical line of the tooth, where the enamel is to end. Yet we see that the organ extends quite a distance below this point; in fact, nearly surrounds the dentine germ. An examination of the section reveals the fact that the nuclei in the reticulum are not developed in that structure below the points (J). Therefore this fact, taken in connection with the general conformation of the parts, clearly indicates that at this point (J) the tooth crown is to be finished, and all below that is the developing root. And it is just as evident also that in its outward growth the tooth passes directly through the remains of what once was the enamel organ, and which now becomes the matrix for the cement substance of the root and the boundary line for the dentine of the same. Inasmuch as this deposit here begins much earlier than that of the cement, it is seen that such a boundary must in some way be provided.

Here probably ends the office of the enamel organ so far as developmental function is concerned. Its life's activities having been spent in erecting to past usefulness a monument composed of the most enduring tissue of the whole body.

The main distinguishing features between the dentine and the enamel are chemical and structural. The same chemical elements enter into the composition of both, but in different proportions. This fact alone would account for a variation in structure, yet aside from this there are other important reasons for this. As we have seen, a specific organ is employed in the production of each, each working in harmony with the other and both for the consummation of the final result. In view of this one would be led to suspect a similarity in their modes of working. In studying these structures the following differences of structure are most prominent:

1. That while one is interiorly absolutely non-vascular the other is decidedly vascular.
2. In one a matrix is provided as a receptacle for the deposit; in the other no such provision is made.
3. In one a reticulated structure is a prominent feature; in the other it is hardly noticeable.
4. In one the deposit occurs in a distinct and specific form; in the other it is semi-homogeneous.

Notwithstanding, however, these well-marked differences, which we believe have often heretofore led investigation wide of the truth, we are convinced that there is very little, if any, difference in the mode of working in each. The dentine organ, as before stated, is developed in, and probably from, the embryonic elements of the submucous tissue. Some time previous to its en-

velopment by the enamel organ a rapid development of blood-vessels occurs at its base. These shoot upward into its substance, rapidly becoming a dense and arborescent system. They run mainly parallel to its long axis, with numerous fine branchings as they approach its upper boundary, where they appear to end in loops. The substance of the organ appears as a granular mass—due to its somewhat dense cellular structure. Its cells are small, variously formed, and are joined by very delicate processes, thus forming another stellate structure analogous to that of the enamel organ and probably also with the same functional characteristics, although with a widely differing environment. Some time previous to the deposit of dentine there occurs what has been supposed to be a metamorphosis of the cells along the border line in contact with the enamel matrix, which now assumes the appearance of a columnar layer at these point. These bodies, the so-called "odontoblasts," as stated above, are only nucleated enlargements of the axial processes of the matrix cells of the enamel organ, which penetrate the dentine organ along this border and are again, by fine processes, joined to the deeper cells of that structure, thus forming a continuous system. The axial connections of these columnar bodies with the matrix cells form the "dentinal sheaths" or tubuli—their axis cylinders—the dental fibres. The branchings of the "tubuli" are a result of a fusion of two or more of these bodies. We are aware that all this is very unorthodox, *but so we see it*. In this connection we should ask a careful study of Plate 7. This section was made from a growing tooth. The space (A) was occupied by the dentine pulp. The "odontoblasts," so-called (B), are left attached by their long processes to the formed dentine. As represented here, their bodies often penetrate deeply into the dentine organ. As a rule, however, they lie nearly in contact with the line of deposit. The delicate processes at the free ends of these bodies by which they connect with the structural elements of the dentine pulp are torn away.

An examination of the dentine pulp at a time when the deposit is in progress reveals the fact of a profusion of granular bodies or nuclei quite similar to those of the enamel organ, which here as there, we may infer, constitute the calcific elements of the deposit. The reticulum of the dentine pulp is by no means as easy of demonstration as that of the enamel. Very careful manipulation and fresh unmounted specimens are the conditions of success in this direction. Plate 8 represents such a structure in the pulp of an adult tooth. Since, however, this occurs where there had been a secondary deposit, an abnormal growth is to be suspected.

Upon examining the pulp of a fresh specimen of growing teeth we find, adjacent to the inner extremities of the odontoblasts, a profusion of

the granular nuclei referred to above as constituting the elements of deposit. In just what manner this deposit is brought about is unknown; but the facts that it occurs in layers or laminae, and also that these granular constituents do not lose their identity in the new formation, are easy of demonstration. By treating the dentine with alkalis we may separate it into its component parts in just the same order in which they were put together. This we have demonstrated before.

The chemical difference existing between the enamel and the dentine seems more easy of a reasonable explanation. In the dentine organ exist just those conditions requisite to cause this difference. With its dense system of blood-vessels, enclosed in unyielding walls, are furnished the conditions for excessive blood pressure required for the passage of those elements (coloids), by transudation or otherwise, which makes this difference.

Since writing the above it has, through some subsequent observations, occurred to me—almost to the point of conviction—that in its inceptive development the dentine germ is indebted wholly to the enamel organ for the stimuli requisite for such a purpose. In other words, the enamel organ is the inceptor of the dentine germ.

We know that no tooth is developed without the predevelopment of such an organ. Even in that type of teeth which have no enamel the formation of an analogous enamel organ is the first inception. This is a fact which cannot be explained by the natural or other selection, or by referring to primitive forms. Its existence, therefore, under such circumstances, would seem to imply that of a necessity it must bear some significant connection with the formation of the dentine germ.

DR. M. H. FLETCHER: The paper we have just heard and the accompanying illustrations evidently represent the expenditure of much labor and time in their preparation. It is only those who are initiated and experienced in such work, that can appreciate the hours of research, and thought and reasoning necessary in such an investigation. In the whole subject of embryology, and the various phenomena connected with it, one will not find more natural barriers and difficulties to overcome in any branch than in undertaking the study of the dental system of animals. It has claimed much attention from our most learned and talented scientists, and is still involved in great obscurity. The most excellent paper just presented, clearly indicates a love for the work which would accomplish great achievements in this direction under favorable circumstances and opportunities.

The illustrations shown in connection with the essay, represent various stages of development

from the dipping down of the mucous membrane, to the development of both enamel and dentine. As to the time of this first appearance and dipping down, the essayist does not differ from other investigators. But the "dental groove," which he speaks of as not always being present, should be called the "dental ridge." Sudduth says on this point: "Concomitant with the formation of the ridge, the proliferation of the cells of the infant layer causes a depression of the subepithelial layer lying immediately underneath. Were we to lift up this thickened epithelial layer, it would leave behind a groove in the underlying tissue. But let it be remembered, that in lifting up the ridge or rampart of epithelial cells, we have made the groove. It is never a groove *per se* but, when formed, is always an artificial product which can be made at will." The "dental groove of writers," as quoted, is therefore now obsolete.

The essayist also says that at this period, "a change is seen to occur at certain points in the cells of the epithelium consisting of an enlargement of the cells and their nuclei, these points corresponding nearly to the position of the future teeth." This enlargement of the cells and nuclei at this stage has not, to my knowledge, been noted by other writers. But some authors speak of a proliferation of the cells, their size remaining the same until the dipping down of the cord has occurred, at which time some investigators have claimed also that the cells of the malpighian layer assume a columnar form. However, the latest investigations seem to show the cells of these layers to be oval or cylindrical shaped until the cord comes into contact with the dentine papillæ, and, after this occurs, they take on the columnar form and evidently become the ameloblasts.

The stirrup shape of the enamel organ spoken of is only the form seen on making sections of the tissue. As a matter of fact, the organ is bell-shaped, forming a hood over the dentine papillæ. It is spoken of as a cap, however, in another part of the paper. At this stage the doctor shows a section in which he claims that, "at the point where the enamel organ embraces the cervical portion of the embryonic tooth, the wall of this organ is folded upon itself, thus bringing both walls into mutual contact." (See Fig. 3.) So far as I know no other author has observed this. Other investigators represent this portion as free from such conditions as described. But since this is not a matter closely concerned in any part of the development it is not of great significance.

The important point in the paper, and that which has the greatest claim for originality, is the theory of the origin of the odontoblasts. After speaking of the numerous lateral processes given off by the ameloblasts or "matrix cells," he says: "And thus is formed the supposed mem-

brane lying between the enamel and the dentine, and which consists simply of a mesh or network composed of the lateral processes of the matrix cells. These matrix cells also send axial processes beyond this border line, and into the dentine organ where nucleated enlargements occur in them. Thus they become those columnar bodies known as odontoblasts." This certainly gives to the odontoblasts an entirely new origin, for they have up to the present been considered as a modification of the cells of the subepithelial tissue in like manner as the ameloblasts are a modification of the malpighian layer. The layer of cells at the summit of the dentine papilla, which come into nearest contact with the enamel organ, are the ones thus converted into odontoblasts.

To claim that any lateral process of a cell becomes nucleated and forms a cell of another class is certainly a perversion of the laws of morphology to some extent; for it would seem that if there are any truths established in this branch of science it is that, when nucleated cells divide, the division of the nucleus—as a rule at least—precedes that of the whole cell. If the doctor could show that the matrix cells generate a second nucleus which passes through this basement membrane, then it would add greatly to the rationality of his theory. The development of the cell, however, is a gradual process from a general to a special state. We can conceive how the subepithelial layer, in the process of differentiation, might develop from the epithelium, or the reverse. But the processes of amelification and dentification are, according to the essayist's own definition, quite different, and, in consequence, would require different kinds of cells—at least, sufficient difference to need the step from epithelial to subepithelial structure before these cells could be converted into organs differing as widely as the enamel organ and the dentine organ. Then, too, in this particular case, there is a great chance of error, for these processes are extremely hard to trace. Legros and Magitot say in regard to the process of the stellate cells: "It is a remarkable fact, that no line of juncture can be discovered where these cells are connected with each other, the various reagents failing to disclose the least trace of it." And this certainly holds good with regard to any processes given out by the ameloblasts at this stage. Nevertheless, this new theory does credit to its author and possibly may be true. But the chances are against it.

The fact that the enamel organ is to be universally found in the earliest stages of tooth development, even in that type of teeth which have no enamel, is not proof of the truth of this theory. For it is certain that many cells act catalytically on their environments. It is therefore not improbable that this action is the influ-

ence given out from the enamel organ, and is necessary for the incipient development of the odontoblast layer.

Reverting to the subject of the enamel organ, we may say that the description is good of the manner in which enamel is probably formed by the "subsuperimposing one upon another of the spherical cells, or nuclei from the 'stratum intermedium,' within the walls of the matrix cells." And also that the lateral processes of the cells and the cell walls may form the boundaries to the enamel prisms. One illustration (No. 6 B) shows the enamel organ with its stellate reticulum to be present over the particular part of the tooth in which the enamel is being deposited. But Sudduth claims there is no deposit of enamel until the reticulum disappears. The illustrations, if properly understood, would disprove Sudduth's theory on this point. That the remainder of the enamel organ form Nasmyth's membrane seem to be pretty well established. But the essayist seems to look upon the existence of this membrane as a myth.

The doctor would make this enamel organ a most versatile affair. For according to his theory it first prepares and forms the enamel, then gives the necessary cells to the dentine organ. Without it he thinks dentine could not be produced. And before it ends its existence he has it enclosing the root of the tooth, and producing the cement which is much less like enamel than dentine. This latter function of the enamel organ is certainly a new one, and it will be difficult to maintain the premises upon which the doctor's conclusion in this connection is based. Since cementum assumes so nearly the form of bone, the two processes of formation must be very much the same, and consequently produced by similar organs. Cementum is claimed—and most properly—to be a subperiosteal product stimulated into growth by the same causes that effect the formation of subperiosteal bone. The difference between it and true bone is possibly due to the confined limits in which this tissue is necessarily deposited. Since the periodontal membrane, according to Sudduth, has the special superintendence of this deposit, and is simply a continuation of the periosteum. The modification compared to bone can be accounted for easily in the manner described. But what part the enamel organ can possibly have in the production of cementum, either primarily or secondarily, is not easy to see. Moreover, the tissues necessary for the production of enamel are not at all necessary for the production of bone or cementum.

As to the source from which the cords of the permanent teeth are derived authors differ. But the latest investigators almost universally believe that the cords for the twenty anterior permanent teeth are developed from the cords of the twenty corresponding temporary teeth, instead of from the epithelium as the essayist thinks, and the cord

of the first permanent molar from the epithelium, that of the second molar from the cord of the first, the second in time giving off a cord for the third and last tooth. There are specimens showing deviations from this rule, but they seem to be mere irregularities.

In closing my remarks I deem it just to say that since there is no standard in this matter, on account of the extreme difficulties surrounding such minute investigations, all that we can do is to compare the work of the essayist with that done by other late investigators. The training and labor necessary even to follow the steps of the established processes and phenomena in this work are not small. And when one has become so familiar with the microscope and the preparation of specimens that he has perfect mechanical familiarity with his work, then comes the original work which he must undertake. But just here we meet with our greatest difficulty, for we have reached the limit of our appliances and reagents. We can now only let the imagination go on and, reasoning from homologies and analogies, form theories and try to establish them. As improvements may hereafter be made in our means of investigation our theories must stand or fall as they are found to be based upon facts or fiction. And it must be remembered that these improvements are generally brought about by the discoveries and the demands of just such faithful workers as our essayist. To him therefore are due the most hearty thanks of all interested in this or in kindred work.

ARE "MEMBRANOUS CROUP" AND DIPHTHERIA IDENTICAL? YES.

Read in the Section on Diseases of Children at the Thirty-ninth Annual Meeting of the American Medical Association, Cincinnati, May, 1888.

BY I. N. LOVE, M.D.,
OF ST. LOUIS, MO.

Since the first paper of Bretonneau, about 1821, at which time our real and definite knowledge of diphtheria had its beginning, down to the present time, the question which forms the subject of this paper has not been decided.

Earnest students and careful observers have answered affirmatively and negatively. I shall not fatigue my hearers by collating the expressions of writers who have accepted one view or the other. I shall present my own opinions based upon a deliberate weighing of all the evidence presented by trustworthy and thoughtful witnesses, and personal clinical observation extending over a period of eighteen years in hospital and private practice.

During the earlier years of my professional life I was uncertain in my position; after reading the views of Virchow, Cohen, West, Flint, and others as able, I was inclined to take a position in the

ranks of dualists. Severe scrutiny of the products of the pen of Bretonneau, Traube, Barthéz, Sanné, and the tribe of unicists, left me inclined to favor their position, but special clinical opportunities and additional arguments of later watchful workers and able annalists like Jacobi and Struempel have enabled me to crystalize my convictions and prompted me to take a position positive and pronounced in favor of membranous croup and diphtheria being identical.

While it may be true, as Hilton Fagge has observed, that the more our knowledge of disease advances the more our distinctions and subdivisions multiply, yet the tendency toward unnecessary multiplications and distinctions without differences should be guarded against most carefully.

Dermatologists have given us half a dozen different terms to be applied to the different forms or expressions of erysipelas when, as a matter of fact, we know that, pathologically speaking, they are all one and the same disease, dependent upon the same germ and only varying in degree, action, or manner of announcement.

So too with fevers, the same disposition was manifested, as was illustrated when for a time typhoid fever, plus malaria as a complication, permitted the new coined term, "typho-malarial fever," to take its place in our nomenclature.

Whether the membrane, as in the so-called true croup, be a fibrinous exudation, superficial and easily stripped from the surface, leaving a smooth mucous surface, only robbed of its epithelium, while that of diphtheria is more of a coagulation penetrating or poured into the mucous tissue—a necrosis, as it were, in which the discharge can be removed only with great difficulty—is not important, it being largely dependent upon the anatomical characteristics of the parts involved.

That the disease is due to a special germ or microorganism, is admitted, and the recognition of this pathological point in the treatment has made a much more favorable showing in the mortality reports.

The growth and development of seed depend much upon their individual virility, favorable soil and surroundings. The expression of every disease varies with the individual victim, and is largely affected by its environment, favorable or unfavorable. A. may have typhoid fever so mild as to lead his physician to fancy he has in hand a simple case of continued fever; an attack of scarlet fever so simple as to be almost frivolous to the unwary; an assault from the dreaded Asiatic scourge—cholera—so mild as to take the form of a gentle intestinal relaxation; an erysipelas suggesting an erythematous flush; a small-pox with pustules few and far between, and little systemic suffering, while B. in the same ward may fall a victim to typhoid, typical; scarlet fever, severe and superbly perfect; cholera, classical, and collapse prompt; erysipelas so excessive as to en-

danger life and occasion an amount of suffering indescribable, and a variola so virulent as to promptly kill, or leave its victim marked in visage repulsive. This being so, then why should not A. be as likely to have diphtheria in a manner so moderate and superficial as to be almost overlooked, and B. so pronounced as to be fatal before the local expression could be observed.

Diphtheria selects by preference the pharynx rather than the larynx. The tonsils are a favorite site for the infection, not alone because of their prominence, but also because, as has been demonstrated, there is frequently to be found an interruption or break in their protective epithelial covering, and also owing to the fact that they are frequently in a vulnerable condition owing to previous or present inflammatory conditions. Then again, pavement epithelium is much more susceptible to attack than the ciliary variety, the latter being a higher grade of organization, of a more complex character, and possessed of greater ability to oppose aggression. When diphtheria attacks the larynx and trachea, which it does, fortunately, very rarely relatively, owing to the ciliary covering being less easily penetrated by the bacillus (possibly the tubercular bacillus makes a primary attack upon this point so seldom for the same reason), the free distribution of mucous glands which flow freely creating an exosmosis rather than a endosmosis, antagonizing absorption and impeding the peril of the adjacent tissues and destructive necroses of the same. At the same time the secreted mucus aids in throwing off the exudations from the surface, and the same causes are an explanation of the failures of the lymphatics of these structures to take up the infectious matter—hence laryngeal and tracheal diphtheria are largely local and unaccompanied by constitutional symptoms and would be a really mild expression of the disease were it not that for mechanical reasons life is endangered.

For similar reasons the circumscribed patches of diphtheria membrane upon the tonsils frequently covering them in their entirety, or their opposing surfaces, are unaccompanied by much constitutional disturbance; glandular involvement, etc., are mild manifestations of the disorder, and by practitioners who intemperately assert that death is the only evidence deciding in favor of a diagnosis of diphtheria, are no doubt sometimes placed in line with non-infectious diseases.

The structure of the mucous membrane, its different elements, as the epithelium, basement membrane, underlying connective tissue mixed with elastic fibres, the blood-vessels, nerves, and gland ducts, all affect materially the pathological plan of action locally and the general involvement. The free flow of secretion from the membrane lining the larynx and trachea, and the nasal cavities favors the separation and ready expulsion of organized exudates, but the difference in the ad-

jacent tissues is manifest in the varying systemic poisoning; in laryngeal and tracheal diphtheria, Bowman's membrane forms a barrier to ready absorption, while nasal diphtheria is deadly dangerous, due to the large number and size of the lymphatic ducts of the Schneiderian membrane, as well as their perfect communication with the lymphatic glands of the neck, all aiding ready entrance into the circulation.

The urine being free from albumen in the majority of cases of croup, is cited as an argument by the dualists to sustain their position, but even granting the fact, it is explainable by reason of the constitutionally mild character of the attack, if the larynx be primarily involved, and the large mortality preventing a fair comparison and complete determination of presence or absence of albumen. The frequency or infrequency of subsequent paralysis presented to prove their position as dualists can be met by the same answer as the above. A very interesting discussion of this subject occurred in the Louisville Clinical Society, January, 1888, and is reported in the *American Practitioner and News*, of February 4. An exhaustive aggregation of arguments from the dualist standpoint are presented by Dr. John A. Ouchterlony. Dr. W. Cheatham, of Louisville, by request of Dr. Ouchterlony, looked up the authorities for the other side and admirably arrayed them in the service of his friend, and he acknowledges that the resulting article comes very near making him a unicist. If there be a difference it is far from clear to his mind.

The argument that the suddenness of the attack and absence of a period of incubation separates croup from diphtheria, is properly met by the statement that examinations of the pharynx and nasal spaces are frequently insufficient, and the mild prodroma which would of necessity occur in primary laryngeal or tracheal diphtheria would probably be overlooked. I suspect that if the majority of cases of croup could tell their own story they would relate the fact that a complete examination, with full illumination of all the available mucousterritory had not been made, and that intelligent and persistent interrogation might have revealed a history of slight loss of appetite and discomfort in swallowing difficult morsels for several days before.

To illustrate this point, I recall three cases of croup, so-called, within my knowledge during the past six months. One case will illustrate the three. Sent for to see a child 4 years old, said by parents to have sore throat, and feared diphtheria; not being in office some hours elapsed and call was cancelled. A few days later mother informed me that she had treated the child with medicine ordered for a neighbor's child with diphtheria, and had countermanded the order for me to call fearing her house would be placarded, and her business—the supplying of the neighbors with

milk—ruined. Five days later I was summoned in the night, but being out another physician was called. Two days later I was called in consultation and found the child dying from pronounced laryngeal diphtheria. Intubation or tracheotomy was offered and rejected. The child died a few hours later and a certificate was given by the attendant giving croup as the cause of death.

The mortality records show an enormous increase of deaths from croup (?) during an epidemic of diphtheria.

One fact which is worthy of notice, and which is an additional argument in favor of the identity of the two diseases, is that the classical treatment for croup has for years been the free exhibition of the mild chloride (coupled with stimulation), with a view to its defibrinating effect. The secretory system has thus been stimulated, and the effect has been to favor the moistening and exfoliation of the exudation and antagonize the disposition to constitutional involvement.

Since the same plan of treatment has been applied to general diphtheria the tendency has been to the securing of a similar result, and the mortality reports present a more favorable showing. By the prompt recognition of the first appearance of diphtheria, and the immediate institution of imperative interference in the shape of free purging with mild chloride, local antiseptics rendering the infectious matter innocuous, and the continuance of constitutional measures which are germicides and stimulators of glandular action, first on the list being the bichloride, benzoate of soda, and large quantities of water, we can without doubt claim accomplishments that are tangible and positive.

I feel strong in the conviction that "croup" and diphtheria are one and the same disease, and that the teachings of pathological anatomy, as well as the clinical symptoms will justify no other conclusion.

3601 Lindell Boulevard.

A NEW METHOD OF TREATMENT OF DISEASES OF THE URETHRA, BLAD- DER, UTERUS AND RECTUM— DRY MEDICATION, DRY SYRINGE.

Read in the Section on Surgery and Anatomy at the Thirty-ninth Annual Meeting of the American Medical Association, May, 1888.

BY ELMER LEE, M.D.,
OF ST. LOUIS, MO.

It is only the fact of defect, or lack of perfection, that permits of progress. Absolute perfection is not attainable. Evolution in medicine as in every other thing promises only progress. But it is a moderate forecast that asserts the certainty that diseases will be mainly conquered, life made more comfortable, and a man's life extended be-

yond the fixed limit of three-score years and ten. The industry of men everywhere enduring and endeavoring to discover means and methods of curing diseases of the race is great as it is noble and good. The probability is that, ere long, some great discoveries will flash out that will expedite progress. I bring my contribution, much or little, valuable or worthless. Perhaps it may help some other one to go a step further.

The urethra of the male is a passageway chiefly concerned in carrying urine from the bladder, having a length of some 23 cm. (8 or 9 inches) between the meatus and the bladder. The size of the urethra is 6 mm. ($\frac{1}{4}$ inch) in diameter, slightly less at the outer end, slightly more at the inner end. Mucous membrane lines the channel throughout, which is continuous with the inner coating of the bladder for urine and the kidney. The diseases of the urethra are similar to the diseases of mucous membranes elsewhere in the body. Inflammation of the urethra may be produced by one of the following causes: 1. Repeated mechanical or chemical irritation; 2. Catching cold; 3. Toxic and miasmatic infection. There is an endless number of known and unknown septic poisons of which many, if not all, have a specific inflammatory action.

My paper is especially concerned at this time with a method of treatment of mucous membranes of canals and cavities accessible to surgical aid. The male urethra is the seat of frequent inflammatory disease, and infection is the common cause, and the diplococci or gonococci of gonorrhœa the

thetic, but the prime question is, how to use the drugs with effect and without harm to the unfortunate patient.

I think it is a matter as to how, more than as to what, to use. My method of treatment of diseases of the urethra is as follows:

1. The employment of alkaloids, salts of alkaloids, glucosides and pure chemicals, in the dry state.

2. The active principles are in the form of granules or small masses mixed with pure cane sugar, and as soluble as the nature of the active agent will admit.

3. The placing of one or more granules at a dose, whether for purposes antiseptic, disinfectant, anæsthetic, astringent, and so on, in the precise region of the disease, and leaving the medication just where it is deposited. As it melts and dissolves and mixes with the secretions the tract or region of tissue will be bathed as the substance finds its way over their surface.

4. The use of instruments adapted for the purpose of carrying the granules in.

The matter of the selection of the medication is in the hands of the surgeon to use that which he may. The form of the remedy is convenient, the dose is accurate, and the method of introducing it into the channel of the urethra, the bladder, the cavity and neck of the uterus and the rectum is clean, economical, elegant, effective and simple. The warmed and oiled instrument is carried down into the urethra until the end defines the inflamed patch, and this it does with ac-

most common cause. The treatment of the urethra for gonorrhœa and other inflammations concerns a vast number of persons.

The methods of treatment are numerous. It is to day, in the light of science, not a question so much as to what remedy or drug is required to destroy the cocci and other bacteria, and which drug is a good disinfectant, and which an anes-

curacy, when the granules are deposited in the urethra and the instrument withdrawn. The size of the granule is such that only the slightest, if any, irritation is caused. There is absolutely no distress as is the case with bougies of gelatine and masses of medicated gelatine and cocoa butter, and so on. The strength of the substance of the granule will determine as to how many to use for one

dose. A single granule of corrosive sublimate of 1 millig. ($\frac{1}{80}$ grain) is equivalent to a teaspoonful of a sublimate solution of 1:2000. Of granules of iodoform, iodol, hydro-naphthol, thallin sulphate and cocaine hydro-chlorate, as many may be deposited as may be needed in the judgment of the surgeon. The solubility of the granules *in situ* is considerably increased on account of the acid secretion of the mucous coat.

In the urethra the salts of alkaloids dissolve in three to six minutes, the alkaloids take a little longer, and the pure chemicals in three to six minutes. The medication is in a form so small and even when mixed and dissolved in the acid secretion, is inconsiderable in volume, a condition which favors thorough medication, in that the whole substance is retained on the mucous surfaces and not expelled as it would be if it were of a solution injected, or of such bulk as would cause distress to the urethra and expulsive contraction in the uterus.

A few days before I left home, my neighbor, Dr. Steele, used the uterine douche and a solution of boric acid in the case of a patient, the object of which was to disinfect the cavity of the uterus of some petrifying *debris*. Some particle of substance was forced into a venous sinus thereby, partial collapse ensuing quickly, which was with extreme effort overcome. Dr. Steele said to me, "Would the *granules* of boric acid not have been equally efficient? I think they would. And would there have been the same risk to life? I think not."

The granules are made of the active principles and pure chemicals and contain absolutely no irritating material. The size of the granule is not to be more than 3 mm. ($\frac{1}{8}$ inch) in diameter, for obvious reasons, and will contain of substance 1 centigram ($\frac{1}{16}$ grain), 1 milligram ($\frac{1}{80}$ grain), and of a few substances $\frac{1}{2}$ milligram ($\frac{1}{200}$ of a grain). The alkametric granules of Frederick Stearns & Co., of Detroit, made chiefly of Merck's pure crystalline salts, are suitable for my method. Also, the dosimetric granules of Chanteaud, in such high favor in France. The granules of the Metric Granule Co., of Chicago, are especially suitable by reason of the uniformity of size of the granule.

I have devised three instruments, which I will presently exhibit to you, as well as my method upon a patient. The short, straight instrument, consisting essentially of a plunger and barrel with its adaptation to a new application, is, through the kind suggestion of my friend, Dr. C. H. Hughes, christened a "dry syringe." It is applicable to the urethra and rectum. The second instrument is 25 cm. (10 inches) long, and consists of a tube and a flexible piston rod, with the proper curve to pass into the deep urethra and bladder. The third instrument is a modification of the dry syringe for the urethra, and is applicable to the

uterus and cervix. The dry syringe for the urethra is for the patient to use under instruction from the surgeon and may be prescribed or supplied to his patient by the physician. The dry syringe for the bladder and uterus are, of course, only safe in the hands of the skilful surgeon.

The time since receiving my dry syringe from the maker was too short to do more than demonstrate the mechanical features of this method. At the next meeting I will bring the results before you of a year of clinical experience with the dry syringe and granules of pure substances in the treatment of diseases of mucous membranes of the pelvic organs.

316 North Ewing Avenue.

THE CARBON COMPOUNDS.

THEIR TRUE PLACE IN THE TREATMENT OF FEVERS—OR THE PARTICULAR TYPES OF FEVER IN WHICH THEY ARE INDICATED—WITH SPECIAL REFERENCE TO THE EMPLOYMENT OF AMMOXIMUM SALICYLATE IN THE TREATMENT OF TYPHOID FEVER.

Read before the Virginia State Medical Society, at a Meeting held in Norfolk, Va., October 21, 1888.

BY S. K. JACKSON, M.D.,
OF NORFOLK, VA.

The older members of this Society may remember that about fifteen years ago (1873) I had the honor of presenting a paper entitled "Some Points in the Pathology of Typhoid Fever which Furnish Indications of Treatment," in which I suggested a plan of treating that disease differing greatly from those usually pursued. I think it due to the Society that it be kept informed of the history of a suggestion in which some interest may be felt, from its having been first made on this floor, and which has since attracted considerable attention.

My object now is, not only to fulfil this obligation, but also to comment upon a modification which has been proposed. And this will lead us to a discussion of the true place of the carbon compounds in the treatment of fevers, and to show that their selection is of much consequence, and becomes almost a matter of mathematical calculation, while their effects can be ascertained with almost mathematical certainty.

The favorable reception of the paper alluded to induced the editor of the *Virginia Medical Monthly* to solicit another for his journal, with fuller details of treatment and reports of cases in which it had been used. These papers evoked a large correspondence; probably necessitated by some unfortunate typographical errors. After correcting these as far as possible by letter, and after the lapse of some ten years, I felt that the results of maturer study and more extended experience should be laid before the profession; and this desire culminated in a paper on the "Ammonia Treatment of Typhoid Fever," read before the

Section of Practice of Medicine, at the meeting of the American Medical Association in Washington, in 1884. This paper was published in *THE JOURNAL* in August of that year—vol. iii, p. 183.

At the solicitation of the editor of the *Physician's Magazine*, this paper was supplemented by another giving reports of cases showing the effect of the sedative salts of ammonia in reducing temperature, and which was published in vol. i, p. 32, of that journal. Numerous letters, some of inquiry, some reporting experiences, some expressing grateful acknowledgments, poured in from all quarters. *THE JOURNAL* in an editorial called attention to the original paper by a kind and favorable comment, and then again on October 10, 1885, gave an abstract and recommended a re-reading of it. My object in making these allusions is merely to show the amount of interest awakened in the subject.

These notices were followed by an exceedingly interesting paper by Dr. J. R. Barnett, of Wisconsin, relating some cases in which he had employed, with the most gratifying results, the treatment as proposed by me, and then giving an account of his experience with a modification of it suggested by himself, viz.: the substitution of ammonium salicylate for those salts of that base which had been proposed and used by me (*THE JOURNAL*, December 11, 1886). This drew from the pen of Dr. J. D. Sullivan, of Brooklyn, N. Y., a paper read before the Fifth District Branch of the New York State Medical Society in May, 1887, and of which a reprint was subsequently published in pamphlet form, giving a report of cases in which he had used Dr. Barnett's modification. This elicited from *THE JOURNAL* (August 6, 1887, p. 179) another complimentary notice of my paper, with the declaration that it would repay a re-reading.

Dr. Sullivan's paper was followed by a paper by Dr. D. M. Wick, of New Hartford, Iowa, published in *THE JOURNAL*, vol. x, p. 164, February, 1888, giving some interesting cases in which he had employed the ammonium salicylate.

The next paper on the subject which has come to my notice, is in course of preparation by Dr. E. S. Ellis, of Manistee, Mich.

The last two numbers of *THE JOURNAL* (September 29 and October 6) contain another elaborate paper by Dr. Barnett, entitled, "The Antipyretic and Abortive Treatment of Typhoid and Remittent Fevers," in which he condenses all that he has written on the use of ammonium salicylate in fevers.

While these several papers manifest an appreciation of the nitrogen compounds in the treatment of those fevers akin to typhoid, they fail to make distinction between this class of fevers and those of malarial origin, and thus ignore the fundamental principle upon which this treatment is based;

and the object of this paper is to show the necessity of this differentiation; for, while the carbon compounds are essential in the one class, they are of no account in the other—that, though they are required in malarial or bilious fever, typhoid fever and fevers of its class as imperatively demand the nitrogen compounds; and as the ammonium salicylate combines the two classes of remedies, it is more properly adapted to that form of fever which seems to be a compound of both classes.

As to the efficacy of this agent in the septicæmic fevers, it is not my purpose now to discuss.

As an analysis of the cases reported by the several gentlemen will confirm the positions for which we are contending, let us glance hurriedly at them.

The cases in which Dr. Barnett reports having tried the "ammonia treatment," and with marked success, were probably true typhoid fever, while the first in which he used the salicylate was, as he says, remittent fever. Several similar cases followed and, being *similar*, must have been of malarial origin. The next was a case of puerperal septicæmia; the next was of the same nature. Then followed some dozen cases, a majority following early abortions, in nearly all of which cellulitis was present. The next was gangrene of the lungs; next the septicæmic state of the last stage of tuberculosis—pneumonitis complicating other affections—next cerebral meningitis. Some twenty-five or more cases are alluded to, but not reported, of typhoid or allied fevers; but, as Dr. Barnett recognizes a close clinical relationship between these and remittent fever, we cannot know to which class they belong.

Dr. Sullivan's cases were mainly of erysipelas, septic cellulitis, puerperal septicæmia and the septic fever of tuberculosis. He had the opportunity of employing the salicylate in only one case of typhoid fever.

Dr. Barnett alludes to a paper by Dr. S. A. Fliesburg, of Hudson, read before the Inter-State Medical Association in July last, but as I am unable to procure it, have no means of knowing the class of cases reported.

Dr. Wick's cases are easily analyzed. He reports five, not one of which can be considered to be typhoid fever. The first he calls a remittent; the second remittent; the third measles; fourth atypical typhoid. The fifth was probably an intermittent.

Thus we obtain from these cases very little or no evidence of the value of the ammonium salicylate in uncomplicated typhoid fever.

While it has been a gratification to receive from practitioners in almost every State of the Union evidences of their interest in, as well as favorable reports of their trials of, the ammonia treatment of typhoid fever, as proposed by me and practiced with marked success for the past forty years, it has also been a matter of some surprise that so revolutionary a treatment, and one for which so

much is claimed, has not attracted the attention of our schools. Might it not be considered a duty they owe to the profession, either to approve suggestions worthy of trial, or to condemn such as are unsound in principle and likely to be harmful?

It may be that the learned professors of our colleges regarded, as Dr. Barnett was inclined to regard, the theories upon which this treatment was based as mere "vagaries;" but Dr. B. declares, as I had already shown, that they had borne "substantial fruit;" and it is reasonable to infer that a tree that could bear "substantial fruit" was not a myth, but a substantial tree. "A tree is known by its fruits." "Men do not gather grapes of thorns or figs of thistles."

Several of the journals have been furnishing us, lately, with details of the treatment of typhoid fever which is pursued by the most eminent and popular practitioners in the great medical centres of the country; but as these plans of treatment differ widely from that proposed by me, it is to be supposed that they are based on entirely different pathological views from those which suggested "the ammonia treatment." The correctness of these views can now only be inferred, until more accurate scientific investigation can be had, from a comparison of results. I have already reported my rate of mortality (which is less than 1 per cent.), and it would be interesting to compare it with that of the other modes of treatment. Dr. Barnett estimates the mortality by salicylate of ammonia treatment as 3 per cent. Of the others we have no reports.

As stated above, Dr. Barnett has proposed the employment of the ammonium salicylate as a modification of my treatment, and the object of this paper is to show to what class of fevers this valuable remedial agent is applicable, and why neither it nor any of its congeners are demanded, nor are particularly beneficial, in pure uncomplicated enteric fever.

In determining the treatment of a case of fever it is important to ascertain what particular form of fever we have to combat. We are not merely attempting to subdue the elevated temperature common to all fevers, but must aim our attack at the agency which has produced the pyrexia. If the former were our aim, the mere application of cold might effect our purpose; but if the latter, we must endeavor to ascertain the pathogenic cause, which, if as yet beyond our reach, can be studied as to its behavior, as to the conditions most favorable to its propagation, as to the agencies capable of destroying or crippling it, and as to the particular lesions caused by it. So far from recognizing any relationship, either "pathological or clinical," between malarial (that is remittent) fever and typhoid fever, I regard these two forms of fever as entirely and essentially distinct and possibly antagonistic—that they do not prevail in the same district at the same time; that they originate

from different causes and require different treatment. I think I am right in declaring these to be the views generally entertained by practitioners in malarious districts.

I have known some physicians to distinguish between them by testing the ability of quinine to control them or not, (a clumsy and unphilosophical mode of diagnosis) which, while distinguishing between the diseases, demonstrates at the same time their diverse character, as well as the fact that the most efficient means we possess for controlling malarial or remittent fever has no power in enteric fever.

While, in making diagnosis between these two classes of fever, I have not been puzzled by the "insensible shading" of which Dr. Barnett speaks, I admit the existence of a form of fever which really seems to partake of the characters of both. As every one who has read my previous papers on this subject will remember, that I was inclined to regard what is called "typho-malarial fever" as a disease *sui generis*, and due to a cause differing from that which produces true typhoid fever, and that I had considered these two forms of fever antagonistic, as stated above. But subsequent observation has inclined me to modify this opinion, having recently seen cases in which the malarial symptoms disappeared and left the typhoid symptoms uncomplicated, and *vice versa*. In a case just recovered the typhoid symptoms disappeared two weeks before convalescence was established. These hybrid cases, as I will show presently, are those in which Dr. Barnett's modification of my treatment is indicated. In these cases I have lately tried it with the most satisfactory results; but in pure uncomplicated enteric fever I have not seen, nor, for reasons which I have already given, did I expect to see, effects comparable to those of the other ammonium salts. These reasons are probably what Dr. Barnett considers "vagaries," but it is gratifying to know that the accurate researches of modern pharmacology are daily adding new facts confirmatory of them.

I do not know that any one contends, at this day, that the different forms of fever originate from the same cause—that the organism causing malarial fever was identical with that causing typhoid or yellow fever. This would be as preposterous as to suppose that small-pox and scarlet fever were caused by the same micro-organism.

In the account of his researches into the hæmatozoön accompanying, if not causing, malarial fever, Osler remarks: "It is very evident that we are dealing here with structures unlike any others which have been described in human blood, and with bodies which have no relation whatever to the spirillæ, micrococci, and bacteria of certain acute diseases." And Laveran declares that "these hæmatozoa have never been met with elsewhere than in the blood of patients suffering from malaria." These hæmatozoa are so distinct

from the typhoid bacillus in their morphology, in their habitats, in their life-history, in the food they require, in their excretions, in the lesions or effects produced in the human system, no one could suspect a relationship between them, or could suppose that the same toxic agents would be equally deleterious to both. Experience and observation have proved that they are not, and have demonstrated that quinine, the great antidote to the malarial poison, has no effect upon that of typhoid fever. This agent has been proved to be actually destructive of the micro-organism of malarial fever. Laveran declares that "he has never seen the peculiar hæmatozoön of malarial fever *after quinine has been taken*, and in order to find it, it must be looked for before any cinchona preparation has been administered." Has this ever been affirmed of the typhoid bacillus?

Whether the theory by which I attempted to explain the efficacy of certain means in these fevers be accepted or not, it is certain that the carbon compounds have more in conquering malarial, and that the nitrogen compounds are most efficacious in typhoid fever. To the former class belongs salicylic acid, and to the latter ammonium, and therefore the ammonium salicylate may be said to belong to both classes. Few practitioners would be willing to substitute salicylic acid for quinine in malarial fever, nor could I be persuaded to dispense with the doubly nitrogenous salt (nitrate of ammonia) for one with less nitrogen in typhoid fever.

The study of these carbon compounds is one of the most interesting engaging the attention of the profession; and by it some curious facts are being daily developed, which are strongly confirmatory of the theory I have advanced.

Brunton says of these carbon compounds "that their chemical nature depends on the arrangement of their constituent atoms, but their physical character depends on the number of atoms." He might also have said that their antipyretic, antiperiodic and antiseptic power increases with the number of carbon atoms which they contain. This rule, as far as their antiseptic power is concerned, is undoubtedly true, especially with regard to those organisms whose peculiar function it is to produce fermentative processes by which there is an exhalation of carbonic acid (CO_2). To see how far this assertion is justified let us glance at the series.

The lowest in the scale; that is, those with the smallest number of carbon atoms, are the alcohols, which are diffusible stimulants, evanescent in their effects. Methyl alcohol, the lowest (CH_3O), produces excitement quickly and runs through its stages rapidly. With ethyl alcohol ($\text{C}_2\text{H}_5\text{O}$) the stages succeed each other slower, but in regular order, and convulsive phenomena appear. Whereas in cenanthylic alcohol ($\text{C}_7\text{H}_{13}\text{O}$) and caprylic alcohol "the stages are irregular and confused and convulsions sooner occur."

While I have spoken of the lower carbon compounds (the alcohols) as *stimulants*, I do not wish it thought that I ignore the modern idea that they are such by destroying the normal balance between the inhibitory and excitor nerves, by paralyzing the former without directly stimulating the latter. This paralyzing effect seems to be in direct proportion to the number of carbon atoms contained, and the law for which I am contending confirms the modern theory alluded to; for, as we ascend the scale still further, the paralyzing or inhibitory effect is still more pronounced.

The next higher alcohol is amyl alcohol ($\text{C}_{10}\text{H}_{22}\text{O}$), from which the powerful agent nitrite of amyl is prepared, which "produces *paralysis of the nerves*" (Brunton).

The ethers and aldehyde each contain but two atoms of carbon, hence their action is rapid and not persistent. But paraldehyde containing $\text{C}_6\text{H}_{12}\text{O}_3$ "is a pure narcotic causing sleep, like chloral."

Chloral and chloroform, the one having two and the other but one atom of carbon, seem to be exceptions to this rule, but this small proportion of carbon may account for the evanescent character of their anæsthetic and analgesic effect, and also for their want of antipyretic and antiseptic power.

As we ascend to the aromatic series of the carbon compounds this fact becomes still more prominent. We then reach carbolic acid (phenol alcohol, $\text{C}_6\text{H}_5\text{HO}$), creasote, resorcin, and hydroquinone, all of acknowledged antiseptic power.

The next step leads us to salicylic acid ($\text{HC}_7\text{H}_5\text{O}_4$), which though admitted to be germicidal, Brunton says of it, "It is much less useful in typhoid fever, and although it has some antiperiodic action, it is not such a powerful remedy in malarial affections as quinine."

The next in order is chinoline ($\text{C}_6\text{H}_7\text{N}$), containing two more atoms of carbon. It is said to be a powerful antiseptic and antipyretic (Brunton). "It has been used in typhoid fever, etc., apparently with benefit," probably because of the nitrogen it contains.

Naphthol ($\text{C}_{10}\text{H}_7\text{OH}$) contains one more atom of carbon than the last and is said to have a therapeutic action on the skin, like tar, which is used with efficacy in several parasitic skin diseases. When absorbed it causes loss of consciousness and convulsions.

Turpentine, a generally recognized antiseptic, contains the same proportion of carbon ($\text{C}_{10}\text{H}_{16}$).

The next higher in the series is one of the newly-proposed antipyretics, whose powers in this respect are unquestioned, viz., kairin, containing C_{11} , or one more atom of carbon. It is a salt of ethyl (C_2H_5)—chinoline ($\text{C}_6\text{H}_7\text{N}$)= $\text{C}_{11}\text{H}_{12}\text{N}$. We next reach the still more powerful antipyretic, "antipyrin," with its fourteen atoms of carbon and two of nitrogen. This climax is surmounted

by the most powerful destructive agent we possess to the malarial microbe, viz., quinine, which contains twenty atoms of carbon ($C_{20}H_{24}N_2O_3H_2O$).

A glance at this list will vindicate the assertion made at the outset, viz.: That the more atoms of carbon which an agent contains the more powerful is its germicidal and, therefore, its antipyretic effect. But this is only true, as we have shown, as far as the malarial poison and its congeners are concerned. For an agent capable of destroying the typhoid fever poison we must look to another class containing more or less nitrogen, which we have heretofore shown is the natural, or nature's antidote to that poison. The reasons for so considering it we will not repeat, but they are so cogent, and the success of the nitrogen compounds has been so decisive as to induce me to abandon all other means in the treatment of typhoid fever. No other reported plan of treatment compares with it in results, and it is not venturing too much to prophesy that it is destined to become the established treatment of this disease.

I hope I have succeeded in showing,

1. The necessity of a diagnosis between malarial and typhoid fevers, which is important on account of their different characters and their requiring different treatment.

2. That it is only the carbon compounds that are particularly efficacious in malarial fevers: as I have heretofore shown that the nitrogen compounds are demanded and are eminently efficacious in enteric fever.

3. That Dr. Barrett's suggestion of the use of salicylate of ammonium is particularly valuable in that hybrid form of fever to which Dr. Woodward gave the name of "typho-malarial," and not in pure typhoid fever.

4. That the carbon compounds generally are only indicated and could only be expected to be useful in those forms of fever which are due to a fermentative process caused by organisms exhaling carbonic acid gas, since they are chiefly destructive of this class of organisms and have little or no toxic effect upon those causing fevers which are accompanied by processes analogous to putrefaction in which ammonia or sulphuretted hydrogen are evolved, *e. g.*, typhus, typhoid, and the septicæmic fevers.

And finally, that these theoretical views exactly correspond with and are confirmed by clinical experience, as no agents have been found so efficacious in malarial fever as the carbon compounds; none more potent in typhoid fever than the ammonium salts; and probably none more valuable in septic fevers than the salts of sulphurous acid. And further, that this clinical experience justifies a reliance upon the use of these excretory products, viz.: carbonic acid, ammonia and sulphuretted hydrogen as agents for the destruction of the several organisms producing them, as being Nature's mode of inhibiting their life-processes, in

accordance with the law "that no organism can live in its own excreta," that is, in the product of its life-processes.

MEDICAL PROGRESS.

BINIODIDE OF MERCURY SPRAY IN TUBERCULOSIS.—DRS. MIQUEL and A. RUEFF have published a work on the treatment of pulmonary tuberculosis by sprays with the biniodide of mercury. The experiments of Dr. Miquel having shown him that the biniodide of mercury is microbicide in solutions of 1 in $\frac{1}{4000000}$, he was induced to try it against pulmonary phthisis, and this he has done in conjunction with Dr. Rueff. They have established spray apparatus at the Rothschild Hospital, and have submitted phthisical patients to the vapors of the biniodide of mercury, or rather the iodo-hydrargyrate of potassium. The following is the formula of the solution employed for the sprays: biniodide of mercury one part, iodide of potassium one part, distilled water one thousand parts, all by weight. But whether medicamentous liquids in the form of spray penetrate into the trachea, the bronchial tubes, and their ramifications is a question that has not yet been satisfactorily solved. Denied by some, this penetration is admitted by others, and appears to have been demonstrated by the experiments of Drs. Miquel and Rueff. It may, however, be observed, that of twenty-seven patients submitted to this treatment nineteen were improved, and eight remained stationary; the improvements were therefore at the rate of 70 per cent. In these cases attenuation of the pulmonary lesions was obtained, and particularly diminution of the expectoration and increase in the weight of the patients. In two cases even the disappearance of bacilli was established.—*Lancet*, Nov. 3, 1888.

TINCTURE OF PHOSPHORUS IN INFANTILE ASPHYXIA.—DR. FARICI has obtained excellent results in the treatment of asphyxia, occurring in the course of broncho-pneumonia in children. He advises the use of the following formula:

R. Cinnamon water 100 grams.
Ethereal tincture of phosphorus 8 drops.
Syrup of ether 20 grams. *m.*

The dose is a teaspoonful every hour.—*Lyon Médical*, September, 1888.

ENEMA FOR CONSTIPATION WITH HÆMORRHOIDS.—

R. Glycerine 60 parts.
Soap 10 "
Fluid ext. rhubarb 40 "
Essence of chamomile 10 drops *m.*

Use as an enema three times daily.—*Revue de Thérapeutique*, October, 1888.

SATURDAY, NOVEMBER 24, 1888.

EDITORIAL CHANGE.

Having accomplished all that he had hoped or expected to accomplish when he accepted the editorship of THE JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION in 1883, and feeling the necessity for diminishing his responsibilities and constant work, the Editor of THE JOURNAL tendered his resignation to the Board of Trustees in the latter part of June last, the same to take effect on the 31st day of December, 1888. At a special meeting of the Board of Trustees held in Chicago, Nov. 9 and 10, 1888, the resignation was accepted, and JOHN B. HAMILTON, M.D., Supervising Surgeon-General of the Marine Hospital Service, and late Secretary-General of the Ninth International Medical Congress, was chosen unanimously to fill the place. He will enter upon the discharge of his editorial duties January 1, 1889. We trust he will have a long and prosperous editorial career.

AN IMPORTANT QUESTION.

"What will be the final effect upon the American Medical Association of the various associations of so-called *specialists*—the American Surgical Association, the Association of American Physicians, the Gynecological Association and all the others?

It will be a sad day for the profession of America when the time-honored A. M. A. ceases to be the medical institution of the country."—*New Orleans Med. and Surg. Journal*, November, 1888.

The question thus stated by our valued contemporary has been asked in a more private way by many of the more thoughtful members of the profession in all parts of the country. That many sincere friends of the American Medical Association, the true representative organization of the medical profession of this country, have looked upon the steadily increasing number of American associations of specialists with anxiety, lest they prove disintegrating and more or less antagonistic to any general and harmonious organization of the whole profession, is well known. And that some of those who have not only taken part in one or more of these specialist organizations, but have actively promoted the combination of all these in the so-called Congress of American Physicians and Surgeons, have been actuated by the desire that the latter should ultimately displace and supersede the American Medical Association, we have adequate evidence. There is now, and has ever been, in the ranks of the medical profession as in the ranks of all other educated classes, a limited number whose mental characteristics lead them to exclusiveness, or a decided disinclination to meet with the mass of the profession on a common platform. This comparatively small number, chiefly resident in the large cities, have never been satisfied with the liberal organization of the American Medical Association. They were represented in the Convention for organizing the National Association in 1846-7, and earnestly advocated a plan of organization that, while it would admit all regular practitioners of medicine to *nominal* membership, would restrict the whole business and management of the Association to a Council of limited number capable of self-perpetuation, instead of the representative plan based upon the State and local societies as reported by the committee and adopted by a very large majority. At a subsequent period, when the rapid development of specialties had commenced, it was this same underlying mental trait that prompted a few of those, in each, to meet by mutual agreement and organize *themselves* into an American Association under by-laws limiting the number to 50, 75 or 100 as the case might be, and making it impossible for any others to gain membership un-

less they were proposed and elected by nearly a unanimous vote of the existing members.

It is on substantially this narrow basis that the numerous American associations of specialists are organized, and every young specialist entering the profession, unless he has some influential friends among the members to propose him, and not a sufficient number of jealous rivals to *blackball* him, he must wait until he has actually achieved sufficient reputation to make his membership necessary to sustain the credit and influence of the association in order to gain admittance. In the meantime every important specialty is represented in the *Sections* of the American Medical Association, into which he can enter without the risk of being blackballed by rivals already in, and where he can mingle with all classes of the profession and have whatever communications or work of merit he presents spread before the profession generally through the columns of *THE JOURNAL*, instead of being hidden in an annual volume of transactions read by few except the members of the special organization before which they were read. The result will be that three-fourths of the young and ambitious specialists will continue to cultivate the acquaintance of the general practitioners by participating in the State societies and through them go to the American Medical Association and its Sections, and thus rapidly develop a National reputation in less time than they would have been kept in waiting to fill some vacancy in the membership of an exclusive specialist organization. Indeed, this result has already been demonstrated. During the last two or three years more work, and that of equally good quality, has been done in the several Sections of the American Medical Association than has been done in the National Associations of specialists.

And so obvious are the advantages of a wider publication of their papers, and their more direct personal contact with the general practitioners, upon whom the specialists must depend for much of their patronage, that very many of the ablest specialists who are active workers in the special societies, are equally active and influential in the Sections of the American Medical Association. Instead of the circle of American associations of specialists, accommodating in the aggregate less than 500 of the 50,000 or 60,000 members of the regular medical profession of the United States, having any serious tendency to supersede the

American Medical Association, it will only serve as a convenient and really useful place in which the small but respectable class of exclusionists can work and dine without personal contact with the sunburned and weatherbeaten general practitioners of the healing art.

THE HYPNOTIC ACTION OF SULFONAL.

Several articles have recently appeared on the action of this new drug, one of which, an inaugural dissertation by MATHES, is a very carefully prepared paper. He has administered sulfonal to tuberculous subjects, cardiac patients, patients with meningitis, acute alcoholism, anæmia, etc. In short, the drug seems to have been tried in all cases, without distinction, Mathes having previously found that it was harmless in certain quantities. His experiments showed that cardiac patients bore the drug as well as phthisical patients. The results of his experiments were that sulfonal had a complete hypnotic action 72 times in 100 cases, incomplete hypnotic action 9 times, and no effect 18 times; in 19 cases accessory manifestations were produced. In most cases it acted better the second night than the first—a fact that makes it much superior to morphine and preparations of opium. The accessory manifestations mentioned consisted in ringing in the ears, slight cephalalgia, giddiness, general fatigue, and in a few cases vomiting. There were, however, no cardiac nor respiratory troubles, and no modification of the appetite or digestion.

The conclusions drawn by Mathes are as follows: 1. Sulfonal is a useful hypnotic agent, though it is not always efficacious. 2. It has the advantage over other agents of having no odor, no taste, and no influence on the essential organs of life. 3. It caused disagreeable effects in only a very small number of cases; and the worst of them was usually insignificant. 4. The dose is variable, and depends on individual susceptibility. Generally a gram is sufficient to cause sleep without accessory manifestations. When these are produced the dose should be diminished. On account of its slow action it should be given at least an hour before the time for sleep. 5. When the insomnia is due to an irritating cough or to pains not clearly neuralgic, the use of sulfonal is contra-indicated. In most true neuralgias, on the contrary, it may be used with benefit.

The hypnotic value of sulfonal has been investigated also by Dr. G. Algeri, in the Asylum for the Criminal Insane at Ambrogiana, his results being published in a recent number of *La Riforma Medica*. Algeri gives records of fifteen cases of mental disease, mania, melancholia, dementia, alcoholism, etc., in which the use of sulfonal gave a calm and regular sleep. The quantity used was from 1.5 to 4 grams. The sleep produced was not accompanied by any alteration of the circulation or of respiration, and was on the average of five hours' duration. No case of disturbance of the stomach was seen, even when the maximum dose was given.

Contrary to the opinion of Algeri, Mathes agrees with Salgo in regard to the slight sedative action of sulfonal in mania and delirium. Garnier, in a recent article (*Progrès Médical*, October 13), thinks there is much promise for the use of the drug in the therapy of the insane, an opinion shared by Rabbas. Expert opinion, therefore, seems to vary but little in regard to the future field of usefulness of sulfonal. Cramer, Fränkel, Kast, Ostreicher, Rosenbach, Rosin, Schmey and Schwalbe confirm the results obtained by Mathes, and speak from personal experience of the remarkable efficacy of sulfonal in producing a sleep absolutely comparable with normal sleep. After a dose of from 2 to 3 grams this sleep lasts 5 or 6 hours without the least modification of the pulse or respiration, as mentioned by Algeri. All unite in declaring it superior to chloral, paraldehyde, and all other drugs.

DIAGNOSTIC BACTERIOLOGY.

WEICHELBAUM has recently shown, in two cases at the Rudolphus Hospital in Vienna, the great diagnostic importance of bacteriology. The first case was that of a workman who had suffered from articular rheumatism for fifteen days. The tibio-tarsal articulation was swollen, and the temperature of the patient was 40.3° C. After the administration of salicylate of soda the temperature fell, and the pains diminished, but soon took on their former intensity. After five days the left knee-joint became affected, and in a few days a small pustule appeared. The spleen was enlarged, and the inguinal glands engorged. Weichselbaum examined some blood taken from the finger, and found the bacilli of glanders. A few

days after this it was learned that three horses of the employer of the patient were dead of glanders. The patient died twenty-two days after entering the hospital. Weichselbaum found glanders-granulations in the skin, subcutaneous and intramuscular tissue, and in the lungs. It was discovered that the patient had not come in contact with the diseased horses, but he had used the blanket of one of them. It is probable, therefore, that infection took place through the respiratory passages.

The second case was somewhat different. A coachman came to the hospital with several ulcerated nodules on his face, neck, and extremities, muco-purulent discharge from the nose, dyspnoea, tumefied spleen, etc. These symptoms taken in connection with the man's occupation, lead to a suspicion of glanders. But when a bacteriological examination was made of the pus of the nodules, no bacilli were found; enormous quantities of the streptococcus pyogenes and streptococcus pyogenes aureus were found, however. The patient died in four days, and at the autopsy Weichselbaum found, besides the furuncles, œdema of the glottis and lungs, and a parenchymatous nephritis in the atrophic stage. The principal disease, therefore, was nephritis, and the furuncles and the nasal affection were secondary infections.

Weichselbaum has also seen two cases in which the anatomical diagnosis at the autopsy, could be made with certainty only by the aid of bacteriology. These were supposed cases of charbon. The patients were brought to the hospital in an unconscious condition, with paresis of the extremities, dilatation of the pupils, etc., and died in about two hours. At the autopsies Weichselbaum found hæmorrhages into the meninges, brain, and mediastinum, a serous exudation into the pleural and abdominal cavities, tumefaction of the spleen, etc. Charbon was suspected, but examination of the blood did not confirm this diagnosis.

EDITORIAL NOTES.

THE ITALIAN SOCIETIES OF HYGIENE will hold their next Congress at Padua in 1890.

A NEW SANITARY CODE has been adopted by the Italian Senate, and will be soon discussed by the Chamber of Deputies.

SMALL-POX is raging to such an extent in many

departments of Italy that the Government has decided to reorganize its vaccination service.

THE RELATIONS BETWEEN ALCOHOL AND RENAL DISEASES is the subject of a debate to be held before the Pathological Society of London on December 4th and 18th.

THE "GAZETTE MÉDICALE DE LIÈGE" is a new French weekly, of 12 pages, the first four numbers of which have been received. It is edited by Dr. Brasseur; assisted by Drs. Merveille and Roskam, and the physicians and surgeons of the hospitals of Liège.

UTERINE TYMPANITES, according to Braun, of Cracow, may be cured by injections of creolin, in a 2 per cent. solution. Braun relates two cases, in one of which labor lasted five days; the foetus was in a state of putrefaction, and the mother's temperature 40°C ., and her pulse 130. In spite of her serious condition the woman recovered.

COCAINE AND OLEAGINOUS SUBSTANCES, when combined, cause a great deal of pain, says the *North Carolina Medical Journal*. In view of the inclination to use vaseline or some such substance with cocaine, especially in operations on the urethra, this is an important point, which possibly has been noted by other observers than Dr. Wood.

THE ALKALOIDS OF COD-LIVER OIL have been investigated by Mourgues and A. Gautier. They describe two fixed bases which accompany the volatile alkaloids: aselline ($\text{C}_{25}\text{H}_{32}\text{N}_4$) from the liver of the *Asellus major*, and morrhuine ($\text{C}_{19}\text{H}_{27}\text{N}_3$) from the liver of *Gadus morrhua*. In the liver of the *Gadus* there are other interesting compounds.

THE NEW MEDICAL STUDENTS IN LONDON this session number 693, including 25 in the London School of Medicine for Women. The English Provincial Medical Schools, as far as heard from, have 201 students. And yet our British brethren complain of overcrowding of the profession, and that too many are rushing into the study of medicine.

DISINFECTION BY STEAM.—Budde has made some experiments to determine whether the tension and movement of steam have a real influence in disinfection, as Koch states. He finds that Koch is correct; that the destruction of the bacilli of charbon may be considered as certain proof of the

efficacy of a method of disinfection. Consequently, anything may be said to be completely disinfected if its deep and less accessible parts have been exposed for at least five minutes to steam at 100°C .

PETERSEN'S BALLOON FOR SUPRAPUBIC LITHOTOMY caused rupture of the anterior wall of the rectum in a case reported by M. Nicaise. An analogous case is reported by Hache. Nicaise's patient was 65 years old, and had already had seven or eight lithotrities performed. The balloon contained 340 grams of water, and the bladder 270 grams.

CHICAGO POST-GRADUATE SCHOOL AND HOSPITAL.—This recently incorporated institution will, it is thought, be opened at an early day. The following are the incorporators and faculty: Drs. N. S. Davis, Sr., J. Adams Allen, H. A. Johnson, A. Reeves Jackson, J. H. Hollister, W. H. Byford, C. T. Parkes, H. T. Byford, Frank Billings, L. L. McArthur, H. P. Newman, W. F. Coleman, F. S. Johnson, Børne Bettmann, Josef Zeisler, R. W. Bishop, Frank Cary, J. C. Hoag, Bayard Holmes, G. W. Webster, and Franklin H. Martin.

THE REPORT OF THE VIRGINIA BOARD OF MEDICAL EXAMINERS.—On another page in this week's issue of THE JOURNAL may be found a tabulated statement of the work done by the Medical Examining Board of Virginia from January 1, 1885, to October 9, 1888. It is to be regretted that we have no figures bearing on a larger number of students examined, and on graduates from a larger number of colleges. The figures given, however, are not without value, and we would call the attention to them of all who have any influence in sending students to the medical colleges of this country, and of all directly interested in medical legislation. Physicians of States that have no practice acts should show that table to the members of the Legislatures, and try to induce them to pass an act similar to the North Carolina or Virginia Acts, thus giving the people that greatest safeguard against incompetent practitioners—an efficient Board of Medical Examiners.

DEATH OF DR. HENRY B. SANDS.—Dr. Sands, the well-known surgeon of New York City, died suddenly in his carriage on Sunday afternoon, while returning from a visit to a patient. Dr. Sands was in his 59th year. He was graduated

from the College of Physicians in 1854, and immediately entered Bellevue Hospital as an interne. In 1857 he became demonstrator of anatomy in the College of Physicians and Surgeons, after serving in which capacity he was elected Professor of Anatomy. About ten years ago he was elected Professor of Surgery, his colleague being Dr. Markoe. At one time or another Dr. Sands has been connected with the surgical department of almost every hospital in New York. As a surgical anatomist Dr. Sands had but few equals, and as a surgeon he was successful and brilliant. He was a very rapid lecturer, which detracted somewhat from his value as a teacher. His writing was not very extensive, but all that he wrote was valuable. To see him operate was an unspoken clinical lecture. His death is a very great loss to the profession in this country.

SOCIETY PROCEEDINGS.

Medical Society of Virginia.

Nineteenth Annual Session, held at Norfolk, Virginia, Oct. 23, 24, and 25, 1888.

(Concluded from page 713.)

WEDNESDAY—EVENING SESSION.

Returning to the minutes in the regular order, as soon as the meeting had been called to order Wednesday night, October 24, prolonged calls were made by the audience upon DR. HUNTER MCGUIRE, of Richmond. Finally consenting to respond, he made an extempore talk on the

FORMATION OF AN ARTIFICIAL URETHRA FOR PROSTATIC OBSTRUCTION.

(See page 695).

DR. HUGH T. NELSON, of Charlottesville, presented his report as Secretary of the

MEDICAL EXAMINING BOARD OF VIRGINIA FROM THE ORGANIZATION OF THE BOARD, NOVEMBER 15, 1884, TO THE PRESENT DATE.

The Medical Examining Board of Virginia is composed of 32 members of the regular profession; 3 from each of the ten Congressional Districts of Virginia, and 2 from the State at large. These 32 members are nominated to the Governor for commissions, by the Medical Society of Virginia, to serve a term of four years. In addition, the Old Dominion Hahnemann Society nominates 5 homœopathic physicians, who are assigned to committees—thus in reality making the Board composed of 37 members.

Every applicant for license to practice medicine, etc., in Virginia since January 1, 1885, who had

not previously secured a license, has been required first of all to receive the permit of this Board before a license could be granted him by any Commissioner of Revenue, Clerk of Court, etc.

The plan for examination of applicants for permits as originally adopted (Nov. 15, 1884) is still in operation, and for thoroughness and fairness has recommended itself to the profession of this State, and to like organizations in other States. Applicants are examined on the eight grand divisions of scientific medicine, namely, chemistry, anatomy, hygiene and medical jurisprudence, physiology, materia medica and therapeutics, obstetrics and gynæcology, practice of medicine, and surgery. The Board is subdivided into eight committees of four members each—each committee having charge of examinations on one of the above-mentioned subjects. In addition, the five homœopathic members who were added to the Board by Act of Legislature, in 1886, were assigned one to each of the following five committees: hygiene and medical jurisprudence, materia medica and therapeutics, obstetrics, practice and surgery.

To each committee is assigned the work of conducting the examinations on a separate subject. Each committee selects and reports the questions in its Section to the Board in session before they are made known to the applicants for examination; and each question thus reported by the respective chairmen of Sections is investigated by the Board, and approved or disapproved—those questions disapproved being remanded to the proper committee for revision or substitution. The standard of requirements adopted by the Board is for the applicants to answer in writing, properly, 75 per cent. of the questions. If an applicant fails to attain of 33 $\frac{1}{3}$ per cent. on any one of the eight Sections, he is refused license, even though he aggregates 75 per cent. as the whole percentage on the eight branches. This was demonstrated to be a necessity from the fact that some applicants entirely ignored the questions in one Section, trusting to make up the deficiency on other Sections.

Two rejected applicants entered on professional work in their respective counties without the permission of the Board, and in open defiance of the law. Both were indicted and punished by the courts. One of the cases was carried to the Court of Appeals of Virginia, which sustained the Board in every point in which its constitutionality was attacked.

A so-called Resident Physician at one of the Virginia Springs, who was a non-resident of Virginia and who had never stood the examination before the Virginia Board, nor had a license to practice in this State prior to January 1, 1885, was duly notified as to the place and time of the last meeting of the Board in Roanoke, July 17, 1888, but did not put in his appearance. After

this Roanoke session, the Secretary received a letter from this *non-resident* Springs Physician, stating that neither he nor the Manager of the Springs deemed it necessary or convenient for him to go to the trouble of going over to Roanoke to undergo the *formality* of examination, and requested that some special arrangement be made for him. As further evidence seemed to indicate an intention to test the law in such cases, the Commonwealth's attorney of Shenandoah County, Va., has put this doctor under bond for appearance before the October term of his Court. There is no reason why physicians from other States should be granted exemptions from the operations of Virginia laws not accorded our own citizens. Steps are being taken to bring to justice two other doctors practicing medicine illegally in Virginia—one in Powhatan County, and one in Goochland County.

The following is a Tabular Statement of Work done by the Medical Examining Board of Virginia, from the date (January 1, 1885,) the Law went into operation through the date of the above Report, October 9, 1888.

INSTITUTIONS REPRESENTED BEFORE THE MEDICAL EXAMINING BOARD OF VIRGINIA.	Total No. of Applicants from each.	Rejections, Total from each.	Certificates issued by Med. Ex. Board of Va.	No. Rejections making Second Applications.	Second Rejections.	Certificates Issued on Second Application.	Incomplete Examinations by withdrawals, etc.
